

Estimating Equilibrium in Health Insurance Exchanges: Price Competition and Subsidy Design under the ACA*

Pietro Tebaldi[†]

February 11, 2024

Abstract

Regulations to design private yet publicly sponsored health insurance markets are increasingly adopted in many OECD countries. Here I combine data and economic theory to analyze the interaction between insurers' competition and the design of premium subsidies in determining equilibrium outcomes. My empirical model includes adverse selection, rich heterogeneity in preferences for vertically and horizontally differentiated plans and accommodates alternative assumptions on pricing conduct. In the context of the Affordable Care Act in the US, I estimate the joint distribution of preferences and expected cost using Californian administrative records on 3.7 million plan choices between 2014-2017, combined with plan and survey data on medical claims. An empirical horse race between conduct assumptions favors oligopoly pricing over perfect competition. Considering alternative subsidy designs shows that, in equilibrium, shifting subsidy generosity toward the young invincibles would lower premiums for all enrollees while increasing enrollment and profits.

*Special thanks go to my Ph.D. advisor Liran Einav, and my dissertation committee Tim Bresnahan, Matt Jackson, and Mark Duggan. I also thank the editor, Thomas Chaney, and four anonymous referees for the helpful suggestions. This article benefited from comments by many participants at seminars and conferences, and particularly from discussions and conversations with Francesco Decarolis, Martin Hackmann, Ben Handel, Kate Ho, and Mark Shepard.

1 Introduction

Welfare losses from adverse selection (Akerlof, 1970; Rothschild and Stiglitz, 1976; Einav, Finkelstein and Cullen, 2010), consumption externalities (Pauly, 1970; Summers, 1989; Mahoney, 2015), and affordability concerns (Wagstaff and van Doorslaer, 2000; Bundorf and Pauly, 2006) justify the growing role of governments in regulating and supporting premium payments in private health insurance markets (Einav and Levin, 2015). These regulations are increasingly relevant across many OECD countries (Colombo and Tapay, 2004), including the United States of America (as reviewed in Handel and Ho, 2021; Handel and Kolstad, 2022), Germany (Atal, Fang, Karlsson and Ziebarth, 2022), the Netherlands (Van de Ven and Schut, 2008; Roos and Schut, 2012), Switzerland (Holly, Gardiol, Domenighetti and Bisig, 1998), Israel (Brammli-Greenberg, Glazer and Shmueli, 2018), Chile (Atal, 2019; Cuesta, Noton and Vatter, 2019), and Uruguay (Fleitas, 2020).

The strategic response of imperfectly competitive insurers to subsidy design was already highlighted for the case of prescription drugs by Decarolis (2015a,b), and further analyzed in Decarolis, Polyakova and Ryan (2020). For insurance covering medical care more broadly, Finkelstein, Hendren and Shepard (2019), Jaffe and Shepard (2020), and Shepard (2022) analyze the premium subsidy program for low-income adults that played a key role in increasing healthcare access in Massachusetts since 2006. These studies consistently draw attention to how individuals and insurers are responsive to regulatory details. Therefore, understanding the ways in which subsidy design impacts market outcomes remains critical for the delineation of future policy.

For this purpose, economic theory provides useful equilibrium comparative static predictions that can be explored empirically. Given theoretical insights, quantifications in a specific context require estimates of the joint distribution of preferences and costs (Einav et al., 2010) and careful modelling of *how* and *how much* insurers' compete.

In this article I begin by noticing that, as seen also in the Netherlands and Switzerland, in the marketplaces introduced under the *Patient Protection and Affordable Care Act* (ACA) in the United States, individuals pay subsidized premiums that may vary with income but not with age. Since expected claims and market-based pre-subsidy premiums increase with age, such subsidy design is more generous toward older individuals. Older age is also a strong predictor of willingness-to-pay for insurance. Therefore, as also noted in Graetz, McKillop, Kaplan and Waters (2018), this design might conflict with the goal of achieving higher levels of insurance coverage while limiting costs. Providing more generous enrollment incentives to costlier individuals increases average cost and puts upward pressure on equilibrium premiums.

Without carefully considering equilibrium responses, one might conclude that a change in subsidy design in favor of younger individuals would penalize older ones. This is the case in [Tebaldi, Torgovitsky and Yang \(2023\)](#), in which demand is estimated nonparametrically but supply and equilibrium adjustments are not modeled, and differences between insurers are ignored. Considering only demand responses, lowering subsidies for relatively older individuals, and increasing subsidies for younger ones would penalize the former, albeit *average* consumer surplus would increase. Additional political economy and equity considerations pose further obstacles to a design under which older individuals would experience premium increases.

Instead, allowing premiums to re-equilibrate leads to different conclusions. Depending on the joint distribution of preferences and costs and on the intensity of competition between insurers, it might be possible to lower subsidies for older individuals, increase subsidies for younger ones, while ensuring that in the new equilibrium *all buyers face lower premiums* while total profits also increase. The intuition is simple: the changes to the subsidy design are such that the composition of enrollees becomes younger, therefore average cost is lower and elasticity of demand is higher. Both forces put downward pressure on premiums, and the resulting reduction can be sufficiently large to compensate older individuals by more than the amount by which their subsidy was lowered to begin with. This argument holds whether insurers exercise market power, although magnitudes depend on pricing conduct.

Other theoretical implications of alternative designs depend more critically on insurers' conduct. For example, market power leads to inefficiently higher prices under "price-linked" subsidies (c.f. [Jaffe and Shepard, 2020](#)), a design also adopted under the ACA and in Switzerland ([Kreier and Zweifel, 2010](#)). If insurers were perfectly competitive, as modeled theoretically in [Azevedo and Gottlieb \(2017\)](#), and empirically in [Einav et al. \(2010\)](#), [Handel, Hendel and Whinston \(2015\)](#), and [Dickstein, Ho and Mark \(Forthcoming\)](#), price-linked subsidies would not generate the strategic responses initially observed by [Decarolis \(2015a\)](#).

Taking stock of these observations, the goal of the remainder of the article is to empirically study competition and quantify alternative subsidy designs in the context of the ACA marketplaces. For this I combine data from the first four years of the Californian marketplace, *Covered California*, with a model of equilibrium pricing that encompasses the ACA regulatory details. Importantly, the model is flexible in terms of the joint distribution of preferences and costs conditional on age and of insurers' pricing conduct, which are key determinants of the equilibrium effects of adjustments to subsidies by age and of the impact of price-linked subsidies.

The estimates of demand are obtained using individual-level premiums and enroll-

ment data for 3.7 million plan choices observed during the 2014-2017 period, which—similarly to [Finkelstein et al. \(2019\)](#); [Tebaldi et al. \(2023\)](#)—I combine with survey measures of uninsurance and subsidy eligibility by age, income, and geographic region. Leveraging the richness of individual-level enrollment records, I estimate a mixed-logit discrete choice model of insurance demand to obtain measures of preferences and demand heterogeneity by age.

The raw data highlights that subsidized premiums are approximately constant in age, while older individuals are significantly more likely to enroll. This is per-se suggestive of age heterogeneity in preferences. To identify demand parameters, I rely on two aspects of ACA regulations. First, discrete variation in cost-sharing reductions induces sharp discontinuities in the actuarial value of the so-called Silver plans at three income thresholds (see also [Hinde, 2017](#); [Lavetti, DeLeire and Ziebarth, 2019](#)). Second, community rating restrictions lead to a “Waldfoegel instrument” identification strategy (c.f. [Berry and Waldfoegel, 1999](#); [Waldfoegel, 2003](#)).¹ Indeed, age-composition is a strong predictor of regional variation in prices. Assuming that—conditional on age and income—preferences are independent from market demographics, I use a control function to correct for premium endogeneity when estimating demand.

As expected, consistently with the literature focusing on demand in health insurance marketplaces (see also [Chan and Gruber, 2010](#); [Panhans, 2019](#); [Saltzman, 2019](#)), I find that younger individuals are less willing to pay for insurance and more responsive to premium increases. On average, those younger than 44 value a ten percentage points increase in actuarial value less than \$350 per-year. Older individuals value this more than \$400, and more than \$700 when older than 55. If monthly premiums increase by \$10, enrollment of individuals younger than 44 would drop by more than 6%, while enrollment among those older than 55 would be 3-3.7% lower. In terms of scope for market power, I estimate an average elasticity between 1.3 and 2 for the “Silver plans” chosen by 68% of enrollees.

To estimate expected insurance costs incorporating adverse selection, the model employs plan-level average claims data (as in [Bundorf, Levin and Mahoney, 2012](#)) and individual-level healthcare spending information from the Medical Expenditure Panel Survey. Expected annual medical spending can vary across individuals and plans. Not

¹The intuition is that the ACA allows insurers to set only one baseline premium for every plan in each geographic region. Then, pre-determined pricing schedules are used to transform baseline premiums to the premiums faced by buyers of different age. Because this regulation links profits across heterogeneous buyers to the same univariate decision, when setting base prices insurers must consider the composition of buyers (see also [Orsini and Tebaldi, 2017](#)).

having access to individual claims data, the baseline model rules out moral hazard,² while it captures selection by letting expected medical spending for an individual vary observably with age, and unobservably with willingness-to-pay for insurance generosity. Variation in the composition of buyers across plans inducing variation in average claims identifies heterogeneity in costs across individuals with different willingness-to-pay.³

Cost estimates indicate adverse selection, due to the strong correlation between preferences for coverage and expected costs. An age increase of ten years implies 38% higher medical spending. An increase in willingness-to-pay (for ten percentage points in actuarial value) of \$500 per year implies 35% higher medical spending.

Prior to considering alternative subsidy designs I use the estimates of the model to set up a horse race between alternative conduct assumptions. Although I fall short of providing a formal statistical test, empirical support for alternative supply models is desirable because, as noted above, conduct impacts the effect size of counterfactual designs. For this exercise to be conceptually sound, it is important to highlight that demand and cost estimates are obtained without imposing any conduct assumption.

Combining demand estimates with the details of rating regulations, subsidy design, and risk adjustment, I can compute average cost, average revenue, marginal cost, and marginal revenue for each plan. I find that risk-adjusted marginal revenues are, on average, 3.5% [2.3%, 4.8%] larger than marginal costs. In comparison, average revenues are, on average, 24.5% [22.9%, 26%] larger than average cost. This shows that—relative to the perfect competition benchmark—oligopoly pricing appears more consistent with observed market outcomes.

When calculating equilibrium under counterfactual subsidy designs, I begin by corroborating the findings of [Decarolis \(2015a,b\)](#); [Jaffe and Shepard \(2020\)](#) in the ACA context, I find that under oligopoly pricing price-linked subsidies increase premiums, and lower enrollment and consumer surplus. This effect is more pronounced in concentrated markets (with 2 or 3 insurers), where I find that premiums would drop, on average, by 13.2% and enrollment would increase by 2.9% (from 0.315 to 0.324) if subsidies were not linked to premiums. In markets with a larger number of insurers, I find a more moderate effect: premiums would drop by 5.3% and enrollment increase by 2.6%. Price-linked subsidies are non distortionary when I simulate competitive equilibria.

²Appendix B shows that my results on the effect of subsidy design are robust to allowing for a degree of moral hazard significantly more severe than what it is assumed in the ACA risk adjustment model ([Pope et al., 2014](#)), or estimated in [Lavetti et al. \(2019\)](#).

³Supplemental Appendix S1 (available online) introduces a novel result providing sufficient conditions for identification of cost curves in selection markets from supply-side assumptions; this adapts to selection markets results dating back to [Rosse \(1970\)](#); [Bresnahan \(1987\)](#).

Shifting subsidy generosity away from older buyers and toward younger ones leads to equilibria in which buyers face lower premiums, while total profits and consumer surplus increase. This result is robust to different subsidy designs and conducts assumptions. Using vouchers, where I increase the under-35 by \$600 and lower the over-35 by \$100, I find that—in equilibrium—premiums for the under-35 would decrease by \$544, while premiums for the over-35 would decrease by \$42 (despite the lower subsidy). Consumer surplus would increase by \$84 per-person per-year, and per-enrollee subsidy would be \$53 lower. Despite the lower per-person subsidy, because total enrollment is higher (under-35 enrollment increases from 0.25 to 0.348, and over-35 enrollment from 0.304 to 0.312) total government spending increases.

Ultimately, the trade-off between lower uninsurance and total government spending is a matter of political economy debate that is far beyond the scope of this article. What I want to highlight here is that, in a market with adverse selection, it is possible to shift generosity of subsidies avoiding that any group of market participants is worse off.⁴ It is also important to note that, although subsidized prices are a key driver of enrollment, there can be other effective ways to incentivize specific groups to participate in the market and affect equilibrium [Cox, Handel, Kolstad and Mahoney \(2015\)](#); [Domurat, Menashe and Yin \(2021\)](#).

There are other reasons to be wary of making (utilitarian) welfare conclusions. First, I do not model competing reasons for individuals to select plans. A growing literature (see e.g. [Domurat et al., 2021](#); [Drake, Ryan and Dowd, 2022](#); [Saltzman, Swanson and Polsky, 2021](#)) documents behavioral biases (e.g. lack of information or inertia) that affect enrollment decisions and might need to be accounted for when calculating consumer surplus. Second, since I discuss counterfactual subsidy designs that would increase total profits, this might trigger entry, a decision that I treat as exogenous and fixed. Common wisdom might suggest that “the more the merrier”, as a larger number of participating insurers would lead to stiffer competition and benefit government and consumers. However, in markets with asymmetric information the effect of entry can be ambiguous, and the interaction between public policy, entry, and market outcomes remains an important object for future research ([Ryan, 2023](#)).⁵ Lastly, here I focus only on equilibrium adjustments to premiums. This is first-order in the Californian marketplace in which the regulator has determined tight requirements for non-premium

⁴I avoid aggregate welfare considerations that would require to put a weight on public spending in this market. For a discussion about why regulators might want to subsidize health insurance although individuals value it less than its costs, I refer the reader to [Finkelstein et al. \(2019\)](#) and references therein.

⁵Indeed, the Californian regulator has been monitoring and sometime limiting entry by large insurers. See e.g. <https://www.latimes.com/business/la-fi-obamacare-unitedhealth-20150116-story.html>.

plan characteristics (see Section 2). However, if insurers could easily adjust other contract characteristics (Miller, Petrin, Town and Chernew, 2019), increasing the share of young invincibles in a market could also trigger quality adjustments and therefore affect consumer surplus in ways that might differ across age groups. For all these reasons, here I focus primarily on enrollment and spending while further work is needed to accurately measure changes in welfare under alternative policies.

Other Related Literature: In addition to the aforementioned articles, here I speak directly to a growing body of work analyzing the effect of different regulations in government-sponsored health insurance markets, reviewed in Handel and Ho (2021). For the United States, the analysis of competition and market design in Medicare Advantage and Medicare Part D is more mature, with focus on subsidies in Decarolis (2015a); Decarolis et al. (2020); Curto, Einav, Levin and Bhattacharya (2021); Miller, Petrin, Town and Chernew (2022). General studies on equilibria in health insurance exchanges are pioneered by Handel et al. (2015), and theoretical implications of alternative policies are the focus of Mahoney and Weyl (2017); Veiga (2020).

The US health insurance market for those younger than 65 has been analyzed primarily through the lenses of the Massachusetts healthcare reform, which served as a blueprint for the ACA (Gruber, 2010). Graves and Gruber (2012) shows the effects on premiums, and Hackmann, Kolstad and Kowalski (2015) the effect on enrollment and costs. The role of mandates is considered in Chandra, Gruber and McKnight (2011), Sommers, Shepard and Hempstead (2018), and then studied under the ACA by Saltzman (2019). Risk adjustment is the focus of Geruso, Layton and Prinz (2019b), McGuire, Schillo and Van Kleef (2020) (which extend the analysis to Germany and the Netherlands), and Saltzman (2021). Panhans (2019) measures adverse selection in Colorado. Fang and Krueger (2022) focus on the ACA impact on labor markets. Geruso, Layton, McCormack and Shepard (2019a) study the interaction policies and the two margins of enrollment and coverage choice. Dickstein et al. (Forthcoming) analyze the relationship between individual marketplaces and small-group insurance. Marone and Sabety (2022) consider the choice of whether or not to provide vertically differentiated plans, Polyakova and Ryan (2019) measure the incidence of subsidies across demographic groups, and Cicala, Lieber and Marone (2019) the regulations limiting insurers' markups. Reviews of the ACA and related literature are provided in Blumenthal, Collins and Fowler (2020) and Handel and Kolstad (2022).

2 ACA Regulations and Data

2.1 Institutional Background and Regulations

As of 2013, 17 percent of US citizens younger than 65 did not have health insurance coverage (Smith and Medalia, 2014). To address this, in 2014 the ACA instituted health insurance marketplaces in each of the fifty states. ACA marketplaces operate separately across states, but they all follow similar institutions and regulations as mandated by the federal reform.⁶ Following the ACA, the Tax Cuts and Jobs Act of 2017, the American Rescue Plan Act of 2021, and the Inflation Reduction Act of 2022 modified certain provisions of the federal law. These changes took place following my study period in this article, yet it will be important for future work to tailor empirical models to the most current regulatory design.

Rating Regions: A state is divided into geographic rating regions—groups of counties or zip codes—defining the level at which decisions by buyers and insurers take place (Dickstein, Duggan, Orsini and Tebaldi, 2015). Insurers can decide whether to offer plans and cover individuals in any given region, as long as they can offer an adequate network of healthcare providers. Different plans are classified into five coverage levels: Catastrophic, Bronze, Silver, Gold, and Platinum.

Metal Tiers: The four metal tiers represent increasing generosity of insurance, measured (and advertised) as “actuarial value”, an estimate of the share of healthcare spending covered by the plan: 60% for Bronze, 70% for Silver, 80% for Gold, and 90% or more for Platinum. Catastrophic plans have higher cost sharing, and generally cannot be purchased by subsidized buyers, nor by buyers older than 30, with few exceptions.⁷

In some states, including California, regulators have determined that, within each metal tier, cost-sharing characteristics are fully standardized across insurers. Deductible, coinsurance, and copayments are fixed. Plans still differ in terms of brand, hospital networks, and possibly Rx formularies. Table 1 summarizes a number of plan characteristics for each metal tier, as mandated by Covered California.

Adjusted Community Rating: One important provision of the ACA is that insurers are not allowed to freely adjust premiums as a function of a buyer’s observable

⁶States can choose between instituting their own marketplace, relying on the federal platform, or adopting a state-federal partnership model.

Table 1: Standardized plan characteristics in 2015 Covered California

Panel (a): Characteristics by metal tier before cost-sharing reductions							
Tier	Annual deductible	Annual max out-of-pocket	Primary visit	E.R. visit	Specialist visit	Preferred drugs	Advertised AV ^(*)
Bronze	\$5,000	\$6,250	\$60	\$300	\$70	\$50	60%
Silver	\$2,250	\$6,250	\$45	\$250	\$65	\$50	70%
Gold	\$0	\$6,250	\$30	\$250	\$50	\$50	80%
Platinum	\$0	\$4,000	\$20	\$150	\$40	\$15	90%

Panel (b): Silver plan characteristics after cost-sharing reductions							
Income (%FPL)	Annual deductible	Annual max out-of-pocket	Primary visit	E.R. visit	Specialist visit	Preferred drugs	Advertised AV ^(*)
200-250% FPL	\$1,850	\$5,200	\$40	\$250	\$50	\$35	74%
150-200% FPL	\$550	\$2,250	\$15	\$75	\$20	\$15	88%
100-150% FPL	\$0	\$2,250	\$3	\$25	\$5	\$5	95%

Source: Section 6460 of title 10 of the California Code of Regulations; May 21, 2014.

characteristics. Characteristics that can affect annual premiums are the buyer’s age (see also [Ericson and Starc, 2015](#); [Orsini and Tebaldi, 2017](#)) and, in some states, tobacco use, but even these adjustments are done in a pre-specified way. California does not allow tobacco-based premium adjustments; therefore, here I focus on age-adjustments, which are central to my analysis.

Considering a rating region, each plan j is associated with a single base premium, say b_j . This is translated to age-adjusted (pre-subsidy) premium using given age adjustment factors, equal for all products. As shown in (1) below, when covering a buyer i under plan j , the insurer receives a revenue R_j^i equal to the product of b_j and the corresponding age adjustment, an increasing function of Age_i .⁸

$$\begin{aligned}
 \text{Insurer decision:} & \quad \text{base premium } b_j \\
 \text{Insurer revenue:} & \quad R_j^i = b_j \times \text{Adjustment}(\text{Age}_i) \\
 \text{ACA subsidy:} & \quad S^i = \max \left\{ 0, R_{j^{2S}}^i - \bar{P}(\text{Income}_i) \right\}, j^{2S} = \text{2nd-cheapest Silver} \\
 \text{ACA premium:} & \quad P_j^i = \max \left\{ 0, R_j^i - S^i \right\}.
 \end{aligned} \tag{1}$$

Premium Subsidies: Although R_j^i is the amount collected by the insurer, enrolled individuals who are eligible for premium tax credits—or simply subsidies henceforth—pay less than this amount. Eligibility and subsidy generosity are determined by the individual household’s annual income: if this is less than four times the federal poverty

⁸The age adjustment is equal to 1 for 21-year-old buyers, and increases smoothly to 1.4 at age 45, and finally reaches 3 at age 64. Details for all ages are shown in Figure 2b.

level (FPL), the individual premium for the second cheapest Silver plan in the region is capped at a federally mandated maximum affordable amount. The resulting subsidy applies to any plan available in the region. This subsidy design is described formally in (1) above. For individual i , the premium of the second cheapest Silver plan in the region is capped at the maximum affordable amount equal to $\overline{P}(\text{Income}_i)$, and the individual-specific subsidy amount S^i is calculated to match this constraint. The premiums for all plans are lowered by S^i ; subsidized premiums must be positive.

Under this subsidy design, for a given income level, individuals of different age can enroll in a Silver plan for exactly the same premium. Differences in subsidized premium across insurers and plans are instead increasing in age, while not varying with income. As a result, all plans with base premiums lower than the second cheapest Silver—which generally include all Bronze plans—are cheaper for older buyers, holding income fixed. Conversely, plans with base premiums higher than the second cheapest Silver—which generally include all Gold and Platinum plans—are more expensive for older buyers.

Cost-Sharing Reductions: Another ACA regulation relevant during my study period is the provision of cost-sharing reductions, available for individuals who enrolled in a Silver plan with income lower than 2.5 times the FPL. For this group, the federal government covers part of their out-of-pocket spending, de facto increasing the actuarial value of Silver plans from 70% to 95% for income levels between 1-1.5 times the FPL, 88% for income levels between 1.5-2 times the FPL, and 74% for income levels between 2-2.5 times the FPL. Covered California achieved these changes in actuarial value in a standardized way, by altering deductible and copayments as summarized in Table 1.⁹

Risk Adjustment: To limit concerns of cream skimming by insurers, the ACA introduced a budget-neutral scheme of risk-adjustment transfers. Simply put, insurers covering enrollment pools that end up being riskier than the market average receive transfers from their competitors; these transfers, by construction, add up to zero within the state. As described formally in Pope et al. (2014), the transfer applying to each plan is calculated by multiplying the state-level average revenue by a plan-level risk score, which can be positive or negative. The score is positive if the enrollees selecting the plan are riskier than the state average, after adjusting for the factors that are already priced in (e.g. age, geography, and metal tier), and it is negative otherwise. Saltzman (2021) studies the implications of ACA risk adjustment for equilibrium outcomes; here

⁹ Following my study period, the Tax Cuts and Jobs Act of 2017 interrupted the funding of cost-sharing reductions, after a legal dispute over the appropriation of federal funds: c.f. *House v. Burwell*, *House v. Price*.

I model it and then hold it fixed throughout my analysis.¹⁰

Other Regulations: Other ACA regulations included two temporary market stabilization programs, reinsurance and risk corridors, income-based tax penalties for individuals not purchasing coverage, and a minimum medical loss ratio of 80%.¹¹ I do not model these explicitly, a simplification partly dictated by data limitations. Incorporating these policies in a tractable empirical model is left to future work.

Coverage options and premiums are set and made public before the beginning of open enrollment, which takes place during the late months of each calendar year. Eligible individuals compare and purchase plans offered in their region of residence; coverage lasts for the following calendar year, as long as premium payments are honored. [Diamond, Dickstein, McQuade and Persson \(2018\)](#) recently discuss the relationship between medical spending and interruptions of premium payments.

2.2 Data Sources and Summary Statistics

2.2.1 Enrollment Files

Covered California provided me with individual-level enrollment files covering the 2014-2017 period, in response to four Public Records Acts requests. For every purchase

¹⁰Risk adjustment in ACA marketplaces does not feature any payments from the government. This is radically different from non-budget-neutral risk adjustment schemes in which the government provides risk-based transfers to each insurer, as it is the case in other federally-sponsored markets such as Medicare Advantage ([Brown, Duggan, Kuziemko and Woolston, 2014](#); [Geruso and Layton, 2020](#)), or Medicare Part D ([Decarolis, 2015a](#); [Decarolis et al., 2020](#)).

¹¹ Federal reinsurance was mandatory between 2014-2016, collecting a fixed amount for every policy sold by any issuer (\$63, \$44, and \$27 in 2014, 2015, and 2016, respectively), and compensating a share (100%, 50%, 50%) of claims between an attachment point (\$45,000, \$45,000, \$90,000) and a cap (\$250,000, equal for all three years).

Risk corridors were intended to facilitate a target variable profit margin of 20% between 2014-2016. Insurers not spending at least 77% of premiums in claims would pay into the system, and insurers spending more than 83% would be eligible for funds. The program was not guaranteed to pay out, since dues could be larger than revenues. For example, in 2014 insurers were due a total of \$2.8 billion, while only owing \$362 million; the program paid only 12 cents for every dollar owed to insurers.

An “individual mandate” tax penalty (see e.g. [Saltzman, 2019](#)) was charged to individuals choosing to remain uninsured, and not qualifying for exemptions. These included “affordability exemptions”. As a result, the individual mandate was only weakly enforced, particularly in the subsidy-eligible population I study in this article. Penalty revenues did not exceed 20% of hypothetical penalty payments ([Miller, 2017](#)), and the mandate penalty was ultimately lifted (starting in 2019) by the Tax Cuts and Jobs Act of 2017.

Medical-loss-ratio adjusted for quality improvements is a measure of the share of an insurer’s collected premiums spent in medical claims and quality improvements. Under the ACA, this ratio must not be less than 0.8. Other studies (e.g. [Starc, 2014](#)) have leveraged these limits explicitly to estimate empirical models of insurance supply. In my application, I do not impose medical loss ratio regulations; I estimate an average medical loss ratio of 0.85, and this remains above 0.8 across all my counterfactuals.

Table 2: Summary statistics

	Individual-level data (person-year)					
	Enrolled (Covered CA)		Eligible (ACS draws)		Surveyed (MEPS)	
	N = 3381971		N = 12433055		N = 20171	
Age	45.8	(11.7)	44	(11.4)	43.8	(11)
Income (FPL %)	214.2	(63.7)	233.6	(75.5)	257.2	(81.1)

Platinum	0.01	(0.012)	4177	(720)	9089	(3890)

Note: The table summarizes data sources. In the Enrolled panel, each observation is an individual in the Covered California enrollment sample, covering all purchases that took place during the 2014-2017 period, restricted to subsidized adults without dependent children. The Eligible panel corresponds to the sample of individuals constructed from the American Community Survey, consisting of subsidy-eligible adults who are either uninsured or privately insured, covering the 2013-2016 period. The Surveyed panel corresponds to the 2014-2017 Medical Expenditure Panel Survey, restricted to individuals who are privately insured and with income between 100-400% FPL. The panels of Market shares and Base premiums report summary statistics from the Covered California enrollment sample. The Average claims panel summarized the 2016-2019 rate review filings matched to the Covered California sample. Standard deviations in parentheses.

event, I observe individual and household identifiers, along with age, zip code, county, rating region, plan identifier, premium paid, and income group. Income is reported in discrete bins, but one can use the pricing regulations in (1) to determine income with higher precision, I use 5% FPL bins.

As in Finkelstein et al. (2019), I narrow my focus to adults aged 26-64, without dependent children, and beneficiaries of premium subsidies. This group accounts for 78% of enrollment in Covered California during my observation period, for a total of 3.72 million individuals. Excluding dependents, who under the ACA can be as old as 25, the coverage decisions for this group are simpler, and easier to analyze. Moreover, since

Figure 1: Premiums by Age and Income

Note: The figure illustrates the relationship between average revenue collected by the insurer (gray line), average subsidized premium paid by the individual (black line), and average difference between Bronze and Silver premiums for the individual (dashed line), as a function of age (left panel) and FPL (right panel). For revenue and premium, each observation is one individual in the Enrollment sample, for the difference between Bronze and Silver premium, each observation is one individual in the Eligible sample. Local polynomial with Gaussian kernel; bandwidth=2 for panel 1a, bandwidth=10 for panel 1b.

off-exchange plans are not eligible for subsidies, excluding the unsubsidized population mitigates concerns that enrollment files may miss many individuals purchasing coverage outside the marketplace.

The top-left panel of Table 2 summarizes the enrollment data. Average age among subsidized adults in Covered California is 45.8 (with standard deviation 11.7), while average income is 214.5 (63.9) percent of the FPL. Individuals pay, on average, \$1470 (\$1264) per-person, per-year, receiving subsidies that are, on average, more than 2.5 times as large. In terms of metal tier, 24% of enrolled individuals choose a Bronze plan, while 68% choose a Silver plan. Gold and Platinum plans are selected more rarely.

Figure 1a plots how insurer revenue, subsidized premium, and the difference between Bronze and Silver premium vary across enrollees of different age. The average amount collected by the issuers increases in age, from \$3000 per-year on average at 26 to over \$8000 for buyers older than 60. According to the ACA subsidy design, subsidized buyers do not face these increases. Premium paid is approximately constant in age, with very small variations around its average value due to differences in plan selection. At the same time, the average difference between the subsidized premiums of Bronze and Silver plans is increasing in age, from approximately \$800 to \$1200 per-year; older individuals have to pay a higher amount to obtain more generous coverage.

The relationship between income and premium is illustrated in Figure 1b. Average insurer revenues do not differ too much across individuals with different income, while premium paid is increasing, since subsidies become lower.

The bottom-left of Table 2 summarizes market shares at the plan level (insurer-year-region-metal-network; N=1382), there are between 3 and 7 insurers active in every region-year combination. Four players—Anthem, Blue Shield, Health Net, and Kaiser—are present across a large number of markets, while the nine remaining insurers are only available in a small number of regional markets, or for a limited number of years. Market shares of Anthem, Blue Shield, Health Net, and Kaiser are, on average, between 4.8-7.3%, but they vary widely across regions and years, reflecting differences in premiums, set of competitors, provider network or brand attractiveness. In terms of metal tier, a single Silver plan covers, on average, 13.8% of enrollees in a region-year pair, about twice as large as the average share of Bronze plans. A Gold or Platinum plan covers, on average, less than 1% of the market.

2.2.2 Rate Review Filings

I use realized claims information as reported in the annual Rate Review Filings (RRF); these are released by the Center of Medicare & Medicaid Services, and publicly available.¹² As in Bundorf et al. (2012); Saltzman (2021), while I observe enrollment at a granular, individual-level data, my cost measures are aggregated to a coarser level, and noisier. Enriching my analysis to incorporate individual-level claims information would be an important extension of my work, which would be particularly relevant to obtain more precise, externally valid measures of the effect of counterfactual policies.

In the RRF, insurers must declare average experienced claims per-member month. For rate review taking place in 2016, the experience period is 2014; for 2017 rate reviews, the experience period is 2015; and so on and so forth. My analysis uses 2016-2019 RRF. I link RRF to Covered California enrollment files using HIOS-14 (a plan-insurer identifier), enrollment year, and metal tier information. The resulting sample of plans for which I observe a measure of realized average claims consists of 1,026 unique insurer-region-year-tier-network combinations, which covers 74% of the 1382 plans I observe in the enrollment data and use in my analysis.¹³ In terms of enrollment, the sample of plans for which I observe RRF information covers 76% of

¹²Source: <https://www.cms.gov/CCIIO/Resources/Data-Resources/ratereview>.

¹³Some plans change HIOS-14 code over time or leave the marketplace. When this is the case, I cannot match enrollment to RRF. Sometimes groups of plans offered by the same insurer in the same year report the same measure of average claims, pooling across metal tiers, or pooling across rating regions. This adds noise to my measures of realized costs.

the 3.7 million individuals included in my enrollment sample.

The bottom-right of Table 2 reports the summary statistics of realized average claims, by insurer and by metal tier. Differences across insurers reflect a combination of plan selection, risk composition of enrollment pools, regional heterogeneity, and differences in firms’ cost functions. Costs vary widely across metal tiers. A Bronze plan records, on average, claims amounting to \$2197 per-enrollee, per-year (with standard deviation \$902). This compares to Silver plans, with average claims for \$3921 (\$1201) per-enrollee-year, and Gold plans, with average claims for \$4847 (\$1543). Platinum plans register much higher claims, with an average of \$9063 per-enrollee per-year.

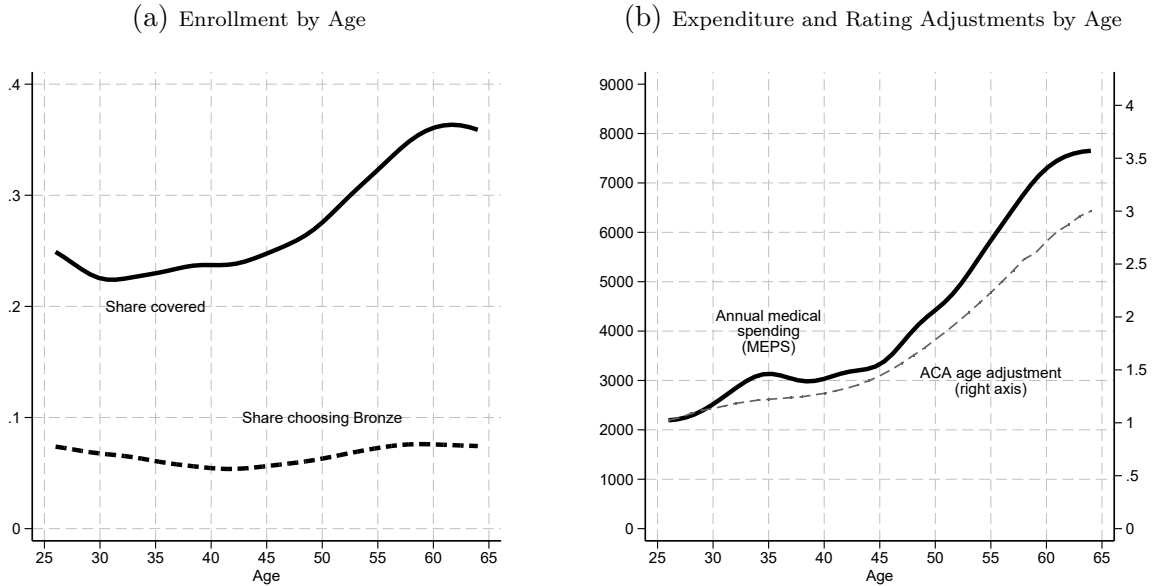

2.2.3 Survey Data

American Community Survey: I construct measures of potential buyers by age, income, rating region, and enrollment year using the American Community Survey (ACS) public use file, downloaded from IPUMS (Ruggles et al., 2015). The procedure is similar to the one adopted by Finkelstein et al. (2019); Tebaldi et al. (2023).¹⁴

As shown in Table 2, eligible buyers are, on average, two years younger and higher income (+20% FPL) relative to marketplace enrollees. Figure 2a shows more details of the relationship between age and the share of potential buyers choosing to purchase marketplace coverage, measured after combining enrollment files with the ACS. The monotone relationship between age and enrollment is evident: the average enrollment probability among under-40 individuals is between 0.22-0.25, this then increases with age until 0.38 for individuals aged between 60-64. Relating this pattern to the fact that average premium paid does not increase in age (Figure 1a) suggests that older individuals are more willing to pay for marketplace coverage. This is supported further by the extent to which the share of individuals choosing a Bronze plan is approximately

¹⁴For every year between 2013-2016, I use the corresponding 5-year ACS sample to measure potential marketplace enrollees for the following enrollment year. Each individual is a potential buyer in the marketplace if they report being either uninsured or privately insured. For every buyer, I observe age, household income, a person weight, and the public use micro data (PUMA) area of residence. Using a PUMA-to-county crosswalk, I assign individuals to the Covered California rating regions. An adjustment to this procedure is needed to account for the fact that the PUMA identifiers can be split across multiple counties, and so in some cases also multiple ACA rating regions. I allocate individuals to each rating region it overlaps using the population of the zip codes in the PUMA as weights. Finally, I merge enrollees and potential buyers for every year, rating region, age, and income cell (in 5% FPL bins). Using person weights, this leaves me with 13,265,960 (synthetic) potential buyers for the 2014-2017 enrollment years, which I then match to the enrollment file. For example, if in the 2013 ACS there are three individuals who are either uninsured or privately insurer, live in Region 5, are aged 50, and have income between 150-155% FPL, and the sum of their person weights is 20, the dataset of potential buyers contains 20 individuals in 2014, Region 5, age 50, and FPL cell 150-155. If there are five enrollees in the same year-region-demographic combination, I measure a total marketplace share conditional on these observables equal to 0.25.

Figure 2: Enrollment, Medical Spending, and Rating Adjustments by Age

Note: The solid (dashed) black line in the left panel illustrates the relationship between age and the probability of choosing a marketplace (Bronze) plan, measured in the Eligible sample. Local polynomial with Gaussian kernel; bandwidth=2. The solid black line in the right panel illustrates the relationship between age and annual medical expenditure in the Medical Expenditure Panel Survey; Gaussian kernel with bandwidth=2. The dashed gray line in the right panel indicates for every age the corresponding ACA age rating adjustment— $\text{Adjustment}(\text{Age}_i)$ in (1)—measured on the right vertical axis.

constant in age, despite the increasing difference in premium relative to other tiers.

Medical Expenditure Panel Survey: The last dataset employed in my analysis consists of the 2014-2017 public use files of the Medical Expenditure Panel Survey (MEPS; <https://meps.ahrq.gov/>), measuring medical spending for a representative sample of the US population. I focus on individuals who are privately insured, with age and household income in the same range as the observations in the enrollment data. The resulting sample of 20171 individuals is summarized in Table 2. Average annual medical spending is equal to \$4111, with standard deviation \$12900. In the next section this data is used to estimate a parameter describing the relationship between age and total medical spending conditional on being insured, controlling for differences across years and macro areas observed in the survey.

Figure 2b plots the relationship between average annual medical spending as a function of age. The graph also shows—measured on the right axis—the ACA age adjustments to pre-subsidy premium. The ratio of a plan revenue from a 64-year-old to revenue from a 26-year-old is 3, while in the Medical Expenditure Panel Survey the ratio of medical spending between the two age groups is higher than 3.5. Average medical spending is slightly higher than \$2000 at 26, approximately \$4000 at 47 and

higher than \$7500 after 60.

3 Empirical Model

3.1 Demand

A potential buyer i is defined by a pair (\mathbf{z}_i, θ_i) , where \mathbf{z}_i is a vector of observed characteristics (age, income, and rating region: $\mathbf{z}_i = (z_i^{\text{Age}}, z_i^{\text{Inc}}, z_i^{\text{Reg}})$), while θ_i is a scalar unobservable which may affect preferences for insurance and expected costs. If the base premium for plan j in region m and year t is b_{jmt} , with $\mathbf{b}_{mt} = \{b_{1mt}, \dots, b_{Jmt}\}$, the premium paid by i when choosing j is $p_{ijmt} = P_j(\mathbf{b}_{mt}, \mathbf{z}_i)$; the function P captures age adjustments and subsidies, as defined by the regulations in (1).

The random indirect utility of i when purchasing j in region m , year t , is defined by $u_{ijmt} = -\alpha_t(\mathbf{z}_i) p_{ijmt} + \delta_{jmt}(\mathbf{z}_i, \theta_i) + \varepsilon_{ijmt}$, where

$$\delta_{jmt}(\mathbf{z}_i, \theta_i) \equiv \beta_t(\mathbf{z}_i, \theta_i) AV_{ij}^D + \boldsymbol{\mu}_t(\mathbf{z}_i) \mathbf{x}_{jmt} + \gamma_t(\xi_{jmt}; \mathbf{z}_i);$$

for $j = 0$, corresponding to not purchasing marketplace coverage, $p_{i0mt} = \delta_{i0mt} = 0$. This is a normalization; the premium for each plan can be interpreted as net of the expected tax penalty. The error terms ε_{ijmt} are drawn iid from the type one extreme value distribution. The premium coefficient $\alpha_t(\mathbf{z}_i)$ varies across years, and across observable characteristics \mathbf{z}_i . The same applies to the coefficient on actuarial value AV_{ij}^D (as observed by individuals upon selecting plans, reflecting cost-sharing reductions), but this coefficient can also vary along the unobservable dimension θ_i . The vector \mathbf{x}_{jmt} collects a constant term, and indicators for insurers, and HMO provider networks, with coefficients collected in $\boldsymbol{\mu}_t(\mathbf{z}_i)$ varying across \mathbf{z}_i and t .

Importantly, the scalar-valued term ξ_{jmt} represents unobservable characteristics specific to a jmt triplet (e.g. quality and breadth of provider networks, drug formularies, or brand preferences), which affect utility through the function γ_t . Being known to insurers, these characteristics can affect pricing decisions, and must be accounted for to avoid endogeneity concerns when estimating demand.

Following [McFadden \(1973\)](#), the probability of purchasing j in region m , year t , for individuals with characteristics $(\mathbf{z}_i, \theta_i) = (\mathbf{z}, \theta)$ is

$$q_{jmt}(\mathbf{z}, \theta) = \frac{e^{-\alpha_t(\mathbf{z}_i) P_j(\mathbf{b}_{mt}, \mathbf{z}_i) + \delta_{jmt}(\mathbf{z}, \theta)}}{1 + \sum_{k=1}^J e^{-\alpha_t(\mathbf{z}_i) P_k(\mathbf{b}_{mt}, \mathbf{z}_i) + \delta_{kmt}(\mathbf{z}, \theta)}}. \quad (2)$$

Given the distribution G_{mt} of (\mathbf{z}, θ) in region m , year t , total enrollment in plan j is

$$Q_{jmt} = \int q_{jmt}(\mathbf{z}, \theta) dG_{mt}(\mathbf{z}, \theta). \quad (3)$$

The difference between the demand model in (3) and standard discrete choice models with heterogeneous consumers (e.g. [Nevo, 2001](#)) lies in how rating regulations and subsidies determine enrollment responses to insurers' pricing decisions.

Taking the partial derivative of enrollment of plan j with respect to the base premium of plan k one obtains

$$\begin{aligned} \frac{\partial Q_{jmt}}{\partial b_{kmt}} &= \int \frac{\partial q_{jmt}(\mathbf{z}, \theta)}{\partial b_{kmt}} dG_{mt}(\mathbf{z}, \theta) \\ &= \sum_{\ell=1}^J \int \frac{\partial P_{\ell}(\mathbf{b}_{mt}, \mathbf{z})}{\partial b_{kmt}} (\alpha_t(\mathbf{z}) q_{jmt}(\mathbf{z}, \theta) q_{\ell mt}(\mathbf{z}, \theta)) dG_{mt}(\mathbf{z}, \theta). \end{aligned} \quad (4)$$

Equation (4) highlights how changes in base premiums do not affect enrollment directly, since the effect on premiums paid by consumers is mediated by the term $\frac{\partial P_{\ell}(\mathbf{b}_{mt}, \mathbf{z})}{\partial b_{kmt}}$. This captures the change in premium of plan ℓ charged to buyers with characteristics \mathbf{z} in response to an infinitesimal change in the base premium of plan k . Under the ACA, the regulations in (1) imply that, if k is the second cheapest Silver plan in the region, $\frac{\partial P_k(\mathbf{b}_{mt}, \mathbf{z})}{\partial b_{kmt}} = 0$, while, for all $\ell \neq k$, $\frac{\partial P_{\ell}(\mathbf{b}_{mt}, \mathbf{z})}{\partial b_{kmt}} < 0$. For other plans, $\frac{\partial P_{\ell}(\mathbf{b}_{mt}, \mathbf{z})}{\partial b_{kmt}} = \text{Adjustment}(z_i^{\text{Age}})$, while for all $\ell \neq k$, $\frac{\partial P_{\ell}(\mathbf{b}_{mt}, \mathbf{z})}{\partial b_{kmt}} = 0$.

3.2 Cost

The insurer expected claims from covering an individual i with characteristics (\mathbf{z}_i, θ_i) under plan j , in region m , year t are equal to

$$\kappa_{jmt}(\mathbf{z}_i, \theta_i) = AV_j^S L_{jmt}(\mathbf{z}_i, \theta_i), \quad \text{where } L_{jmt}(\mathbf{z}_i, \theta_i) = e^{\phi_{jmt} + \eta(\mathbf{z}_i, \theta_i)}. \quad (5)$$

Claims are the product of the actuarial value of a plan (for some plans $AV_j^S \neq AV_{ij}^D$ due to cost-sharing reductions) and the expected total health expenditure of the individual, $L_{jmt}(\mathbf{z}_i, \theta_i)$, which may vary with individual and plan characteristics. Differences in claims across individuals define the main feature of a selection market: buyers with different preferences have different risk and expected insurable costs. Differences in claims across insurers, regions, and years, reflect differences in provider networks, negotiated prices, and insurers' strategies to manage their members' access to healthcare.

Importantly, the cost model specified in (5) does not allow expected medical spending to vary with coverage generosity, ruling out "moral hazard" (c.f. [Einav and Finkel-](#)

stein, 2018). In Appendix B I relax this assumption, estimating cost functions and reproducing my main results for a range of moral hazard parameters.

At the plan level, expected average cost is equal to

$$AC_{jmt} = \frac{1}{Q_{jmt}} \int \kappa_{jmt}(\mathbf{z}, \theta) q_{jmt}(\mathbf{z}, \theta) dG_{mt}(\mathbf{z}, \theta), \quad (6)$$

and I assume that the observed average claims are equal to νAC_{jmt} , where the shock $\nu \geq 0$ is iid across jmt , and such that $\mathbb{E}[\ln(\nu)|G(\mathbf{z}, \theta), \mathbf{x}, \boldsymbol{\xi}, \mathbf{b}] = 0$.

3.3 Identification

3.3.1 Parametric and Functional Form Assumptions

The parametric assumptions on $\alpha_t(\mathbf{z})$ and $\delta_{jmt}(\mathbf{z}, \theta)$ are detailed in Appendix A; all parameters are allowed to vary flexibly by year, and across seven six-years-wide age bins: $A^1 = \{26, \dots, 31\}$, $A^2 = \{32, \dots, 37\}$, ..., $A^6 = \{56, \dots, 61\}$, $A^7 = \{62, 63, 64\}$. The result is a set of 644 parameters. The definitions of $\beta_t(\mathbf{z}, \theta)$ and $G(\theta|\mathbf{z})$ imply that the coefficient on actuarial value is log-normally distributed with year-age-bin-specific parameters. Unobserved heterogeneity and observed demographics are independent: $G_{mt}(\mathbf{z}, \theta) = G_{mt}(\mathbf{z})G(\theta)$, where $G_{mt}(\mathbf{z})$ is observed.

On the cost side,

$$\eta(\mathbf{z}, \theta) = \eta^{\text{Age}} z^{\text{Age}} + \eta^{\text{WTP}} \frac{\beta_t(\mathbf{z}, \theta)}{\alpha_t(\mathbf{z})}, \quad \text{and} \quad \phi_{jmt} = \phi_t^1 + \phi_m^2 + \phi^3 \text{Insurer}_{jmt}. \quad (7)$$

This allows individual medical spending to vary with age, and—to model adverse selection—with the willingness-to-pay for generosity of coverage. The remaining cost parameters are a combination of a constant, year, region, and insurer indicators.

3.3.2 Control Function and Actuarial Value Discontinuities

Identification of demand relies on regional variation in premiums conditional on age-bin and year, on discontinuous variation in actuarial value of Silver plans across buyers with different income, and on variation in the set of insurers and plans across markets.

To obtain instruments for premium, the ACA marketplaces are a setting in which the presence of rating restrictions across demographic groups leads to an intuitive Waldfoegel IV (c.f. Berry and Waldfoegel, 1999; Waldfoegel, 2003). Insurers set base premiums responding to the distribution of demographic characteristics in a rating region, $G_{mt}(\mathbf{z})$, since this affects the shape of Q_{jmt} and AC_{jmt} as shown in (3) and (6). Identification assumes that, *conditional* on a buyer’s age and income, preference

Figure 3: Demand Identification: Control Function and Actuarial Value Discontinuities

(a) Share of under-35 and base premiums

(b) Cost-sharing reductions and AV discontinuities

Note: The figure illustrates the variation underlying identification of premium and actuarial value coefficients. The left panel shows the histogram of the share of potential buyers younger than 35 for each jmt combination in the data. The figure also plots the linear relationship between b_{jmt} (measured on the right vertical axis) and the instrument, $\int \mathbf{1}[z^{\text{Age}} \leq 35] dG_{mt}(\mathbf{z})$, with confidence intervals. See also Supplementary Appendix Table S1. The right panel is a binned scatter plot of the share of enrollees selecting a Silver plan as a function of income (as % of FPL). The linear relationship between the two variables is allowed to vary discontinuously at the three cutoff values corresponding to the discontinuity in actuarial value of Silver plans due to cost-sharing reductions (c.f. Section 2).

do not depend on the distribution of demographics in the same geographic area, yet this affects base premiums, which should be higher in relatively older regions, and vice-versa (see also Orsini and Tebaldi, 2017; Polyakova and Ryan, 2019). Formally,

$$\mathbb{E}[\xi_{jmt}|G_{mt}, \mathbf{z}, \mathbf{x}] = 0, \quad \text{while} \quad \mathbb{E}[b_{jmt}G_{mt}|\mathbf{z}, \mathbf{x}] \neq 0,$$

implying $\mathbb{E}[P_j(\mathbf{b}_{mt}, \mathbf{z})G_{mt}|\mathbf{z}, \mathbf{x}] \neq 0$.

To obtain a control function one can use the residual $\hat{\xi}_{jmt}$ of a regression of base premium projected on product characteristics and share of potential buyers in the region-year who are aged under-35 (the excluded IV):

$$b_{jmt} = \lambda^{35} \int \mathbf{1}[z^{\text{Age}} \leq 35] dG_{mt}(\mathbf{z}) + \lambda^{\text{Tier}} + \lambda^{\text{Year}} + \lambda^{\text{Insurer}} + \xi_{jmt}. \quad (8)$$

Regression results and F-statistics are reported in Supplemental Appendix Table S1, the variation in the instrument and the corresponding variation in b_{jmt} are illustrated

in Figure 3. The first stage OLS estimate of the effect of age-composition of potential buyers on base premium is $\hat{\lambda}^{35} = -5208$, with robust standard error 896. This implies that a 0.1 increase in the share of potential buyers aged under-35 corresponds to a \$521 reduction in base premium.

To identify the effect of actuarial value on indirect utility, as governed by $\beta_t(\mathbf{z}, \theta)$, the ACA marketplaces feature discontinuities in AV_{ij}^D across the cost-sharing reduction thresholds (see Table 1). This institutional feature, which has also been used in Lavetti et al. (2019) to identify demand and cost responses to coverage generosity, implies that at three income thresholds Silver plans become suddenly less attractive, and that the choice to enroll in the marketplace is either costlier or it leads to lower coverage.

The three discontinuities correspond to $z_i^{\text{Inc}} = 150, 200, 250$; the actuarial value of Silver plans drops from 95 to 88, then from 88 to 74, and finally from 74 to 70. As shown in Figure 3, the strongest effect is observed at $z_i^{\text{Inc}} = 200$, when Silver plans become suddenly worse than Gold and Platinum plans. The 16% drop in actuarial value induces a 9.8% reduction in the probability of choosing a Silver plan.

3.3.3 Cost Identification

To identify cost parameters my approach is similar to the one in Bundorf et al. (2012), since I observe demand at the individual level while costs are measured at the plan level. Identification of plan-level determinants of costs is standard, yet here I need to allow costs to vary also within plan across individuals who differ in age and unobservable willingness-to-pay for coverage.

Using a simplified notation, the intuition is as follows. Let u_i denote the utility for coverage of individual i . After controlling for a rich set of plan characteristics, and for the age composition of buyers, the “residual average cost” for plan j can be written as

$$C_j = \int c(u_i) dF(u_i | i \text{ chooses } j), \quad (9)$$

where the function $c(u_i)$ is our object of interest, and $F(u_i | i \text{ chooses } j)$ describes the composition of buyers of j in terms of preferences for insurance. In its simplicity, (9) highlights the key requirement for identification of $c(u_i)$: *variation in the composition of buyers— $F(u_i | i \text{ chooses } j)$ —across plans for which the researcher can assume that differences in the function $c(u_i)$ are known, or controlled for using observables.* In other

Figure 4: Identifying Variation for η^{WTP}

Note: The figure shows a scatter plot and OLS fit of the residual of log-average claims adjusted for actuarial value and projected on region, year, insurer, and age-composition of the plan’s enrollees (Y-axis) on the share of buyers with WTP for AV ($\frac{\beta_t(\mathbf{z}, \theta)}{\alpha_t(\mathbf{z})}$) above the population average (X-axis). Observations are weighted by enrollment, each representing a jmt combination for which average claims are available. This variation identifies η^{WTP} , a positive relationship indicates $\eta^{\text{WTP}} > 0$.

words one needs shifters of buyers’ composition excluded from cost functions.^{15,16,17}

Considering now the details of my application, I need to identify the cost parameters in equations (5) and (7). The Medical Expenditure Panel Survey (see Figure 2b) allows

¹⁵Examples of these shifters include variation in the set of competing plans (a version of “BLP instruments”, c.f. [Berry, Levinsohn and Pakes, 1995](#)), or variation in the composition of potential buyers in terms of sociodemographic characteristics affecting willingness-to-pay for insurance (a version of “Waldfoegel instruments”, c.f. [Waldfoegel, 2003](#)).

¹⁶Although a nonparametric inversion of equation (9) with respect to $c(\cdot)$ is theoretically feasible, it would require (arguably never observed) full support variation in $F(\cdot|i \text{ chooses } j)$ across j . Therefore, a parametrization similar to the one I adopted in equations (5) and (7) is necessary.

¹⁷Following a similar intuition, Supplemental Appendix S1 discusses how data on average claims could be replaced by supply-side equilibrium assumptions to obtain sufficient conditions under which costs functions are identified. This extends the well-known inversion of first order conditions which dates back to [Rosse \(1970\)](#); [Bresnahan \(1987\)](#) to markets with asymmetric information. When claims are available one can then compare observed costs to those estimated under different assumptions on supply, and thus make an informed choice between alternative models of insurer behavior (see Section 4.2).

me to calibrate the parameter η^{Age} , which governs the age evolution of average annual medical spending when insured.¹⁸ Then, as discussed above and illustrated in Figure 4, identification of η^{WTP} relies on the empirical relationship between average claims and composition of enrollment in terms of $\frac{\beta_t(\mathbf{z}, \theta)}{\alpha_t(\mathbf{z})}$ (derived from the demand estimates), after controlling for actuarial value, region, insurer, and age composition. Intuitively, if residualized claims are higher for plans covering a larger share of individuals with high $\frac{\beta_t(\mathbf{z}, \theta)}{\alpha_t(\mathbf{z})}$, as it is the case in Figure 4, $\eta^{\text{WTP}} > 0$, and vice versa.¹⁹

3.4 Estimation Results

Estimation follows the steps detailed in Supplemental Appendix S2.

3.4.1 Demand Estimates

The full set of demand parameters is reported in Supplemental Appendix Tables S2 and S3. Supplemental Appendix Table S4 shows the impact of the control function on demand estimates. Omitting $\hat{\xi}_{jmt}$ would lead to estimates of premium coefficients between one and two percent lower, and to estimates of willingness-to-pay between four and ten percent lower.

Table 3 illustrates how demand for ACA-sponsored insurance varies with buyer’s age. For each of the seven age bins used for estimation, the table summarizes the distribution of willingness-to-pay for actuarial value. The table also reports extensive margin semi-elasticity of demand—measured as the percentage drop in the probability of purchasing marketplace coverage if all annual premiums increase by \$120—and average own-price elasticity of demand for Silver plans, equal to the percentage drop in the share of buyers selecting a Silver plan if the plan’s premium increases by 1%. The extent to which “older buyers demand more” is consistent with intuition and with patterns in the raw data.

Average willingness-to-pay for a 10% increase in actuarial value increases steadily

¹⁸For this purpose I minimize

$$\frac{1}{N_{\text{MEPS}}} \sum_{\ell \in \text{MEPS}} \left\| Y_{\ell} - e^{\eta^{\text{Age}} \text{Age}_{\ell} + \text{Year}_{\ell} + \text{Region}_{\ell}} \right\|, \quad (10)$$

where Y_{ℓ} is the annual medical spending of individual ℓ observed in the survey, and Region_{ℓ} is a Medical Expenditure Panel Survey macro area. The parameter η^{Age} is very robust across specifications and estimated precisely; see Supplemental Appendix Table S5.

¹⁹More formally, note that equation (7) restricts the way in which insurer, year, and region affect medical spending. Given these restrictions, and since I assume that $\mathbb{E}[\ln(\nu)|G(\mathbf{z}, \theta), \mathbf{x}, \boldsymbol{\xi}, \mathbf{b}] = 0$, the residual correlation between AC_{jmt}/AV_j^S and the density of $\frac{\beta_t(\mathbf{z}, \theta)}{\alpha_t(\mathbf{z})}$ within a given jmt combination pins down η^{WTP} .

Table 3: Summary of Demand Estimates by Age Group

	Age 26-31	Age 32-37	Age 38-43	Age 44-49	Age 50-55	Age 56-61	Age 62-64
Mean WTP for 10% AV increase	249.6 (9.3)	293.8 (10.2)	333.5 (12.7)	395.8 (10.9)	507.5 (14.4)	684.8 (16.4)	853.5 (20.7)
St. Dev. of WTP for 10% AV increase	202.6 (5.7)	231.3 (6)	250.1 (6.7)	304.4 (6.1)	373.3 (7.2)	495.5 (9.2)	609.3 (11.4)
% Change in Enrollment if +\$120/year in all Premium	-7.434 (0.203)	-6.822 (0.224)	-6.552 (0.215)	-5.69 (0.136)	-4.86 (0.108)	-3.832 (0.097)	-3.137 (0.078)
% Change in Silver Enrollment if +1% in all Silver Premiums	-2.356 (0.074)	-2.478 (0.081)	-2.113 (0.059)	-2.272 (0.06)	-1.887 (0.047)	-1.732 (0.033)	-1.492 (0.026)
Control Function: Year-Specific Cubic Polynomial of First-Stage Residuals	Yes	Yes	Yes	Yes	Yes	Yes	Yes
Year-Specific Parameters	Yes	Yes	Yes	Yes	Yes	Yes	Yes
Insurer-Year Fixed-Effects	Yes	Yes	Yes	Yes	Yes	Yes	Yes
N. Individuals	2335251	2050631	1814069	1764925	1822717	1841849	803613

Note: The table summarizes the estimates of preferences for insurance and sensitivity to premiums conditioning on different age groups. The reported parameters are functions of the demand parameters in Supplemental Appendix Tables S2 and S3. Standard errors in parentheses, obtained as the empirical standard deviation across 100 independent random draws of the demand parameters using the estimated variance-covariance matrix. The WTP for a 10% AV increase is equal to the ratio $\frac{\beta_t(\mathbf{z}, \theta)}{\alpha_t(\mathbf{z})}$, this varies across individuals both unobservably with θ , and observably with age, year, and income.

with age, from \$263 among those aged between 26-31, to \$343 between 38-43, \$526 between 50-55, reaching the average value of \$892 among those aged between 62-64. This average increase is accompanied by a larger variance: the standard deviation at 26-31 (32-37) is \$210 (\$232), while at 56-61 (62-64) it is more than twice as large, equal to \$516 (\$616).

Increasing all annual premiums by \$120 (third row of Table 3) is equivalent to lowering subsidies by \$10 per-person, per-month, while holding fixed insurers' decisions. I find that this would lower participation of buyers younger than 31 by 7%, compared to 6.5% among those aged between 32-37, and 6% among those aged between 38-43. The extensive margin response to a change in all premiums is much smaller for older buyers. Conditional on age being between 56-61, if all premiums increase by \$120 enrollment drops by 3.7%. For the oldest age bin, 62-64, I estimate that average extensive margin semi-elasticity is equal to 3.1%.

Supplemental Appendix Figure S1 shows the entire distribution of willingness-to-pay and extensive margin response to premium across individuals. These estimates of how marketplace demand responds to subsidies complement (and align with) the estimates of closely related parameters obtained in other studies.²⁰

²⁰Using discontinuities in subsidies in the pre-ACA Massachusetts marketplace, Finkelstein et al. (2019)

The fourth row of Table 3 shows the estimates of the elasticity of Silver enrollment to Silver premiums. This is calculated as the percent change in enrollment in Silver plans if the premium of all Silver plans (which varies by age-income-region-year) increases by 1%. The elasticity of under-50 individuals is between 1.8-2%, while for older individuals this is between 1.4-1.8%.

Interpreting these estimates it is important to highlight that my model of plan choice is static, and does not consider plan switching and consumers’ inertia or state dependence (see e.g. Drake et al., 2022; Saltzman et al., 2021). The extent to which older individuals are less sensitive to premium changes might denote that they have higher inertia (or switching costs), or that the exogenous churn in and out of the marketplace is higher among younger enrollees (as one would expect considering that at younger age labor market shocks and changes to household structure are more frequent). If this was the case, the higher participation of young invincibles obtained in my counterfactuals might not only increase average elasticity in a static sense, but also lower incentives for “invest and harvest” pricing strategies (which I do not model).

3.4.2 Cost Estimates

The full set of cost estimates is reported in Supplemental Appendix Table S6. Table 4 summarizes the key parameters governing heterogeneity in medical spending across buyers who differ in age and willingness-to-pay for actuarial value, and the differences in average costs across age groups for Bronze and Silver plans.

The estimate of η^{Age} derived from the Medical Expenditure Panel Survey is equal to 0.038 (Supplemental Appendix Table S5). This indicates that, on average, one year of age corresponds to approximately 3.8% higher expected medical spending. While age is observed, and partially accounted for by the regulatory age rating adjustments, willingness-to-pay for actuarial value varies unobservably conditional on age.

The parameter η^{WTP} shows that this unobservable dimension of preferences for insurance is positively correlated with medical spending. Table 4 shows that the point estimate of η^{WTP} is equal to 0.07, statistically significant at any conventional level. This implies that a \$100 increase in $\frac{\beta_t(\mathbf{z},\theta)}{\alpha_t(\mathbf{z})}$ corresponds to approximately 7% higher expected medical spending. Given the range of $\frac{\beta_t(\mathbf{z},\theta)}{\alpha_t(\mathbf{z})}$ shown in Supplemental Appendix Figure S1a and Table 3, even conditioning on age, income, and year, willingness-to-pay

find enrollment dropping about 25% for every \$40 increase in monthly premium. Applying a nested logit demand model to data from California and Washington, Saltzman (2019) estimates that a \$100 increase in all premiums would induce 3.3-3.7% reduction in marketplace enrollment. In Tebaldi et al. (2023) we adopt a nonparametric approach and estimate that, if all 2014 monthly premiums increased by \$10, the probability of enrollment in Covered California would have been 0.018-0.067 lower.

Table 4: Summary of Cost Estimates

Parameters of $\eta(\mathbf{z}, \theta) = \eta^{\text{Age}} z^{\text{Age}} + \eta^{\text{WTP}} \frac{\beta_t(\mathbf{z}, \theta)}{\alpha_t(\mathbf{z})}$			Estimator, N. Obs.	Data Source	Region FE	Year FE	Insurer FE
Age	η^{Age}	0.0379 (0.0021)	NLLSQ, N=20171	2014-17 MEPS	Y	Y	N
WTP for 10% AV increase (\$100/year)	η^{WTP}	0.0803 (0.0104)	NLLSQ, N=1026	2016-19 RRF	Y	Y	Y

Insurer Expected Average Cost at Observed Premiums							
	Age 26-31	Age 32-37	Age 38-43	Age 44-49	Age 50-55	Age 56-61	Age 62-64
Bronze Enrollees	1030 (136)	1421 (169)	1861 (203)	2581 (247)	3647 (272)	5334 (263)	7503 (240)
Silver Enrollees	1311 (137)	1821 (164)	2361 (205)	3336 (220)	4742 (229)	7571 (201)	11208 (364)

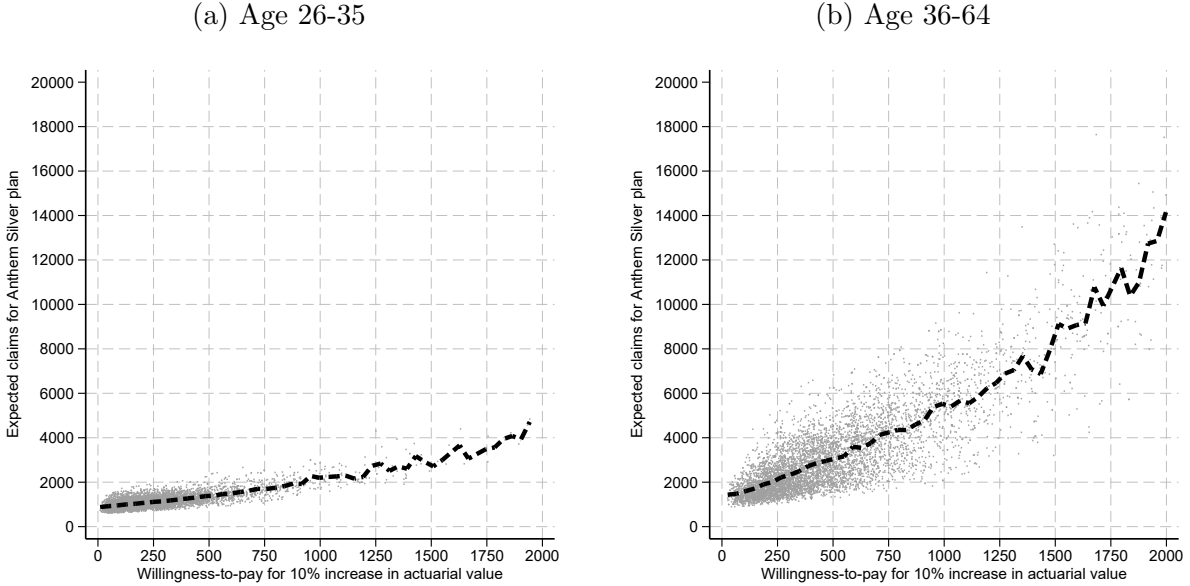

Note: The top panel shows the estimates of the two parameters of the function $\eta(\mathbf{z}, \theta)$, governing the heterogeneity in expected medical spending across individuals. The full set of non-linear least squares estimates is reported in Supplemental Appendix Table S6. The bottom panel shows the estimated average cost across Bronze and Silver enrollees, conditional on different age groups. Standard errors in parentheses, obtained as the empirical standard deviation of cost estimates obtained across 100 independent random draws of demand parameters (using the estimated variance-covariance matrix).

for actuarial value can vary by more than \$700, corresponding to 50% higher expected cost.

The estimates of $\eta(\mathbf{z}, \theta)$ are the distinguishing feature of a selection market: average and marginal cost curves for a given plan jmt are not constant, varying as a function of base premiums. Holding base premiums fixed at the observed levels, the bottom of Table 4 summarizes the value of expected average claims for Bronze and Silver plans, conditioning on the seven age bins used for demand estimation. These estimates depend on $\eta(\mathbf{z}, \theta)$, but also on ϕ , which collects year, region, and insurer-specific cost parameters (c.f. equation (7)).

For Bronze plans, expected average claims are equal to \$1148 per-person, per-year when the enrollee is aged between 26-31, \$1507 when between 32-37, almost \$2000 when between 38-43, and progressively increasing to more than \$7000 for the oldest group, aged between 62-64. Silver plans have higher average claims, reflecting both higher actuarial value ($AV_j^S = 70\%$, instead of 60%) but also a different risk selection: enrollees of Silver plans have higher $\frac{\beta_t(\mathbf{z}, \theta)}{\alpha_t(\mathbf{z})}$. As a result, the average claims of Silver plans when enrolling someone aged between 26-31 are \$1435, 25% higher than the estimate for Bronze plans, and 7.2% higher than the difference that would be explained by the increased actuarial value, holding risk selection fixed. This would be \$1339, computed as $\$1148 \times \frac{0.7}{0.6}$.

Figure 5: Empirical Relationship Between Preferences and Expected Cost

Note: The figure illustrates the joint distribution of willingness-to-pay for coverage and expected cost obtained after combining demand and cost estimates. The graph is generated by randomly drawing 10,000 individuals from $G(\mathbf{z}, \theta)$. For each draw, I compute willingness-to-pay for a 10% increase in actuarial value ($\frac{\beta_t(\mathbf{z}, \theta)}{\alpha_t(\mathbf{z})}$), and expected cost if the individual enrolls in a Silver plan, offered by Anthem ($\kappa_{jmt}(\mathbf{z}, \theta)$, where j is Anthem’s Silver plan in mt). The figure then consists of a scatter plot of these quantities, overlaying this with a local polynomial smoothing of the two quantities. The left panel is conditional on $z^{\text{Age}} \leq 35$, the right panel is conditional on $z^{\text{Age}} > 35$.

The relative difference between Silver and Bronze expected average claims is increasing with age, reflecting the larger premium differences following the ACA rating regulations. When selecting a Silver plan, someone older than 50 must have unobservably higher $\frac{\beta_t(\mathbf{z}, \theta)}{\alpha_t(\mathbf{z})}$ relative to someone younger making the same choice. Among enrollees who are 56 or older, average claims for those selecting a Silver plan are between \$7500-\$10300, 35-40% higher than the claims for those selecting a Bronze plan.

The relevance of heterogeneity and adverse selection in this application is highlighted in Figure 5: higher willingness-to-pay corresponds to higher expected cost. This relationship is steeper for older individuals. Among those under 35, an increase in willingness-to-pay from approximately zero to \$1000 corresponds to a cost increase from \$1000 to slightly more than \$2000. When considering individuals aged 35-64, the same difference in preferences corresponds to a cost increase from \$2000 to \$6000. Even conditioning on a specific value of cost, there is significant heterogeneity in preferences, and vice versa. The joint distribution summarized in Figure 5 is the key primitive one needs to study market design in a health insurance marketplace.

4 Equilibrium and Market Conduct

Before considering counterfactual policy design, it is necessary to model expected profits incorporating ACA regulations, and to seek empirical support for alternative assumptions about insurers' conduct. I assume that insurers understand the regulations (including subsidy adjustments to premiums and floors to subsidized premiums) and have perfect foresight of competitors' premiums.

4.1 Rating Regulations, Risk Adjustment, and Profits

Each insurer f offers the plans in the set $\mathcal{J}(f)$ in region m , year t . The expected profit of insurer f in mt is a function of the base premiums $\mathbf{b}_{fmt} = \{b_{jmt}\}_{j \in \mathcal{J}(f)}$. Expected total revenues for each product $j \in \mathcal{J}(f)$ are equal to

$$R_{jmt}(\mathbf{b}_{fmt}, \mathbf{b}_{-fmt}) = \int \text{Adjustment}(z^{\text{Age}}) b_{jmt} q_{jmt}(\mathbf{z}, \theta) dG_{mt}(\mathbf{z}, \theta);$$

where $q_{jmt}(\mathbf{z}, \theta)$ depends on $(\mathbf{b}_{fmt}, \mathbf{b}_{-fmt})$, including age adjustments and subsidies, as shown in (2). Expected total costs are instead equal to

$$TC_{jmt}(\mathbf{b}_{fmt}, \mathbf{b}_{-fmt}) = \int \kappa_{jmt}(\mathbf{z}, \theta) q_{jmt}(\mathbf{z}, \theta) dG_{mt}(\mathbf{z}, \theta).$$

To model risk adjustment I follow the ACA formula (see e.g. [Pope et al., 2014](#); [Saltzman, 2021](#)), as described in details in Supplemental Appendix S3. For every plan $j \in \mathcal{J}(f)$, the risk adjustment transfer is

$$RA_{jmt}(\mathbf{b}_{fmt}, \mathbf{b}_{-fmt}) = Q_{jmt} \underbrace{\frac{\sum_k R_{kmt}}{\sum_k Q_{kmt}}}_{\substack{\text{average premium} \\ \text{in region-year}}} (\text{Relative Risk}_{jmt} - \text{Relative Adjustment}_{jmt}).$$

In words, the per-enrollee risk adjustment transfer to plan j in region-year mt is the product of average premium in the region and a difference between a relative risk measure and a relative premium measure.

The risk adjustment formula is constructed to ensure that transfers sum to zero. Plans receive positive transfers if they cover costlier-than-average individuals, after controlling for actuarial value differences and premium adjustments. The other plans face negative transfers, which are larger when enrollees are, on average, less risky, after controlling for actuarial value and premium adjustments.

Expected profits for insurer f in region-year mt combine the above definitions and account for multi-plan insurers: omitting the dependence on $(\mathbf{b}_{fmt}, \mathbf{b}_{-fmt})$ to simply

the notation,

$$\Pi_{fmt} = \sum_{j \in \mathcal{J}(f)} R_{jmt} - TC_{jmt} + RA_{jmt}.$$

Different subsidy designs imply different R , TC , and RA functions, by altering the relationship between $(\mathbf{b}_{fmt}, \mathbf{b}_{-fmt})$ and the composition and risk selection of individuals choosing different plans.

4.2 Evidence on Insurers’ Conduct

I consider two alternative models of insurer conduct: static multi-product Nash pricing (as in [Bundorf et al., 2012](#); [Starc, 2014](#); [Decarolis et al., 2020](#); [Saltzman, 2021](#); [Curto et al., 2021](#)), and perfect competition à la [Azevedo and Gottlieb \(2017\)](#), in which every plan breaks even in expectation as adopted recently by [Dickstein et al. \(Forthcoming\)](#).²¹ Although I compute counterfactuals under both assumptions, I am in the position to investigate whether the data supports one over the other.

Formally, multi-product Nash pricing requires that, for every insurer f , the following FOC are satisfied for every $j \in \mathcal{J}(f)$, every m , and every t :

$$\frac{\partial \Pi_f}{\partial b_{jmt}} = \sum_{k \in \mathcal{J}(f)} \frac{\partial R_{kmt}}{\partial b_{jmt}} - \frac{\partial TC_{kmt}}{\partial b_{jmt}} + \frac{\partial RA_{kmt}}{\partial b_{jmt}} = 0. \quad (11)$$

Perfect competition requires that, for every jmt ,

$$\Pi_{jmt}^{\text{AG}} = R_{jmt}^{\text{AG}} - TC_{jmt}^{\text{AG}} + RA_{jmt}^{\text{AG}} = 0. \quad (12)$$

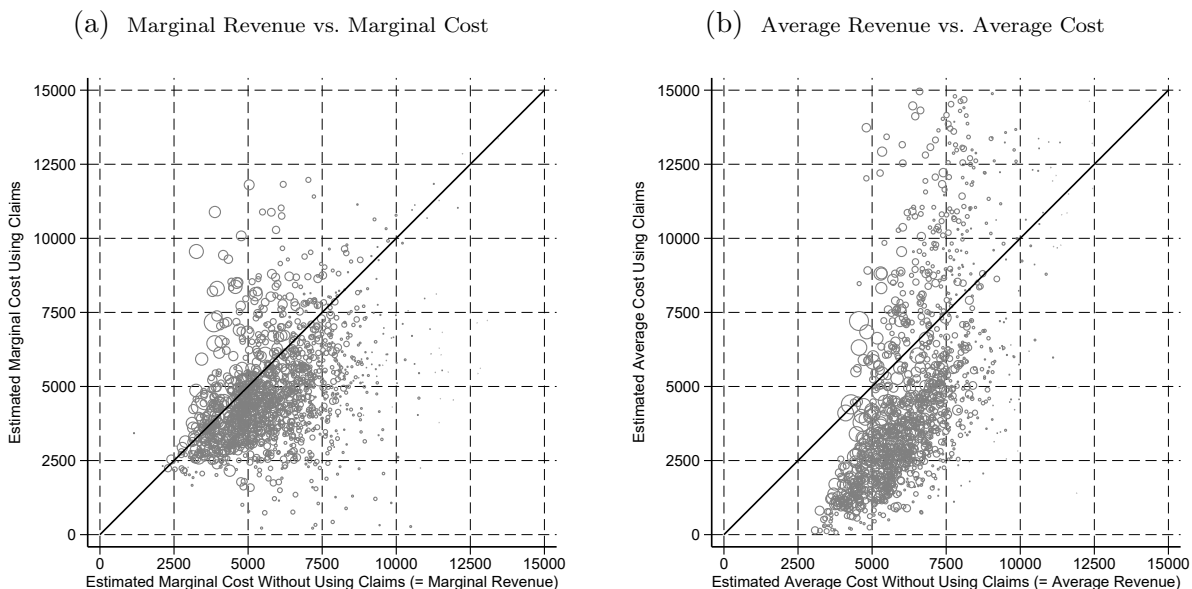

In this expression, the superscript AG indicates that the demand function $q_{jmt}(\mathbf{z}, \theta)$ is modified to let an infinitesimal fraction of “behavioral” buyers choose a given plan independently from changes in premiums or other characteristics.²²

Figure 6 compares estimated and model-predicted marginal and average costs under alternative conduct assumptions. This is not a formal test, but it shows that observed data and estimated primitives are more consistent with multi-product Nash pricing than average-cost pricing. A formalization of this procedure, in which—rather than

²¹Future work could consider even more complex models of imperfect competition between insurers, allowing for strategies to be dynamic, or firms uncertainty about demand and cost functions (see e.g. [Saltzman and Lucarelli, 2021](#)).

²²I assume that a fraction of individuals equal to 0.001 chooses iid uniformly across the J plans. This ensures equilibrium existence (c.f. [Azevedo and Gottlieb, 2017](#)). Profits in this case are “almost” zero, rather than zero, as it will be the case in Tables 5 and 6.

Figure 6: Multi-Product Nash Pricing vs. Perfect Competition

Note: The left panel shows the comparison between per-enrollee risk-adjusted marginal costs estimated assuming multi-product Nash-in-Prices without using claims (these are equal to marginal revenue), and per-enrollee risk-adjusted marginal costs estimated using observed claims. The right panel shows the comparison between per-enrollee risk-adjusted average costs estimated assuming perfect competition without using claims (these are equal to average revenue), and per-enrollee risk-adjusted average costs estimated using observed claims. Markers are weighted by plan enrollment, each observation is a jmt combination.

imposing supply assumptions during estimation—the researcher compares alternative models of conduct before running counterfactuals, represents an important venue for future work. For the case of markets without adverse selection, statistical tests to discriminate between models of conduct are known since [Bresnahan \(1987\)](#).

The comparison between the two models relies, albeit somewhat implicitly, on the possibility to identify cost curves in a selection market imposing supply-side assumptions, rather than observing costs directly. While here I discuss my findings informally, a new, formal and self-contained identification result is provided in [Supplemental Appendix S1](#).

In [Figure 6a](#), the horizontal axis corresponds to the per-enrollee marginal revenue for every jmt combination in the data. Nash pricing predicts that this would be equal to per-enrollee risk-adjusted marginal cost, following [equation \(11\)](#). The vertical axis corresponds to the estimate of this quantity for every jmt . It is important to recall that [\(11\)](#) has not been used as a moment or constraint for the estimation of demand and cost. The resulting scatter plot is concentrated around the 45-degree line. The enrollment-weighted average difference between per-enrollee marginal revenue and per-enrollee risk-adjusted marginal cost is \$293.46 (95%-C.I.: [217.09, 369.84]). The enrollment-weighted average ratio $\frac{\partial \Pi_f}{\partial b_{jmt}}/R_{jmt}$ is 0.035 (95%-C.I.: [0.023, 0.048]).

For comparison, Figure 6b repeats the same procedure to explore the discrepancy between average revenue and risk-adjusted average cost. Perfect competition predicts that the two quantities would be equal, and the distribution should be close to the 45-degree line. As shown in the figure, relatively to Figure 6a this seems not to be the case. For a large number of jmt combinations estimated risk-adjusted average cost is significantly lower than average revenue, providing evidence against perfect competition. The enrollment-weighted average difference between R_{jmt}/Q_{jmt} and $(TC_{jmt} + RA_{jmt})/Q_{jmt}$ is \$1331.12 (95%-C.I.: [1236.73, 1425.50]). The enrollment-weighted average ratio Π_{jmt}/R_{jmt} is 0.245 (95%-C.I.: [0.229, 0.260]), corresponding to a departure from the model assumption 14 times as large as under Nash pricing.

One additional piece of evidence in support of modeling insurers as not perfectly competitive is provided by the estimated medical loss ratio. Despite not imposing a constraint in estimation, I calculate average medical loss ratio at the observed base premiums to be approximately equal to 0.85 (Table 6). This is above the minimum value of 0.8 mandated by the ACA, while still lower than the perfect competition value of one.

A static oligopoly model seems to perform well. However, one could note how the extent to which marginal revenues are, on average, slightly higher than marginal cost is consistent with the omission of dynamic considerations. If consumers have inertia, as documented in Drake et al. (2022); Saltzman et al. (2021), static marginal revenues do not account for a the (positive) continuation value of keeping current enrollees. As discussed above, since younger individuals have higher churn and have been estimated to have lower inertia, the policies increasing their participations that I discuss below could also reduce dynamic pricing incentives.

5 Subsidy Design and Equilibrium Outcomes

5.1 Price-Linked Subsidies vs. Vouchers

I begin by comparing equilibrium under ACA subsidies and equilibrium under fixed vouchers: subsidies that do not adjust endogenously with base premiums. Jaffe and Shepard (2020) call the ACA design a “price-linked subsidy”: the market sponsor determines the maximum premium individuals should pay, and adjusts subsidies to insurers’ decisions accordingly. One alternative is to use an “equivalent” voucher: the subsidy received by every individual is fixed to the (price-linked, endogenous) amount received under the ACA. This varies then by age, income, region, and year, but it is not adjusted in equilibrium.

Table 5: From ACA Price-Linked Subsidies to Equivalent Vouchers

	Multi-Product Nash pricing				Perfect Competition			
	2-3 insurers 27 region-years		4-7 insurers 49 region-years		2-3 insurers 27 region-years		4-7 insurers 49 region-years	
	ACA subsidy	Equivalent voucher	ACA subsidy	Equivalent voucher	ACA subsidy	Equivalent voucher	ACA subsidy	Equivalent voucher
Share enrolled	0.32	0.36	0.28	0.29	0.27	0.27	0.28	0.28
2nd cheapest Silver b_j	4127	2998	2709	2559	2387	2387	2116	2115
Share in Bronze plans	0.15	0.14	0.13	0.13	0.16	0.16	0.14	0.14
Medical-loss ratio	0.82	0.8	0.89	0.84	1	1	1	1
ΔCS_i relative to ACA	-	90	-	30	-	-00	-	1
Average subsidy	5705	4187	3249	3258	2713	2709	2223	2211

Note: Simulated market outcomes under alternative subsidy designs and different region-year markets. The left panel corresponds to multi-plan Nash pricing, where equilibrium is simulated in every region-year by finding the vector of base premiums \mathbf{b}_{mt} that minimizes the distance between the left- and right-hand side of Equation (11). The right panel corresponds to perfect competition à la [Azevedo and Gottlieb \(2017\)](#), where equilibrium is simulated in every region-year by finding the vector of base premiums \mathbf{b}_{mt} that minimizes the distance between the left- and right-hand side of Equation (12). The ACA subsidy corresponds to the regulations described in (1) in Section 2. The Equivalent Voucher corresponds to setting subsidies equal to the level of the ACA subsidy, and then computing equilibrium removing price-linked adjustments of subsidies to the second cheapest Silver plan in a region-year pair. Share enrolled and second cheapest Silver base premium are computed as averages across region-years, weighted by number of eligible individuals. The share in Bronze plans, medical-loss ratio, and average subsidy are computed as averages across region-years, weighted by enrollment. ΔCS_i indicates the average, per-person annual consumer surplus, which is reported in differences from the equilibrium under ACA price-linked subsidies.

The transition from a price-linked subsidy to a fixed, equivalent voucher increases the own-premium semi-elasticity for the second cheapest Silver plan in the region-year. Under the ACA design, when this plan increases its base premium buyers do not face premium increases, the only effect is to lower other plans’ premiums. Under Nash pricing, switching to an equivalent voucher implies that the second cheapest Silver plan has incentives to charge lower premiums, and this effect should be larger in less-competitive, more-concentrated markets.

[Jaffe and Shepard \(2020\)](#) discuss this mechanism formally for the case of single-plan insurers, in which the subsidy-setting plan is the cheapest; this was the case in the pre-ACA Massachusetts marketplace. As anticipated in their appendix, the main difference in the ACA context is that insurers offer multiple plans, and that subsidies are determined to target the second cheapest Silver, rather than the cheapest Bronze.

Table 5 shows how market outcomes vary when adopting ACA price-linked subsidies or equivalent vouchers. The left panel shows results obtained assuming multi-product Nash pricing, the right panel assumes perfect competition. In the latter case, outcomes do not vary across the two subsidy designs (equilibrium premiums depend only on enrollees expected costs): price-linked subsidies are non-distortionary in perfectly competitive markets. Under Nash pricing, adopting equivalent vouchers affect equilibrium outcomes, since it implies a lower second cheapest Silver base premium.

The price distortion due to linking subsidies to insurers’ decisions is larger markets that are more concentrated. In small regions (2-3 insurers), second cheapest base premiums drop by 13.2%, from \$4127 to \$2998; in larger regions, with more than four participating insurers, the drop is smaller, from \$2709 to \$2559 (-5.3%). Cheaper Silver plans lead to a lower share of buyers choosing a (high deductible) Bronze plan.

Accounting for adjustments to all premiums, and consequent changes in plan selection and composition of enrollment pools, the Nash-pricing equilibrium under equivalent vouchers implies slightly higher marketplace enrollment, increasing from 0.315 (0.266) to 0.324 (0.273) in small (large) regions. The corresponding increase in annual per-person consumer surplus relative to the ACA design is between \$24-\$28. In regions with less than four insurers average subsidies drop from \$5070 to \$4694; in larger regions from \$3388 to \$3345. Insurer profitability is also higher, as medical-loss ratio drops from 0.82 (0.89) to 0.8 (0.84) in small (large) regions.

Despite differences in the specific policy and market structure, the comparisons between equilibrium under ACA price-linked subsidies and vouchers are similar to the results in [Jaffe and Shepard \(2020\)](#). They argue that fixing vouchers to a specific level requires regulators to have prior knowledge of insurers’ costs yet show that—for reasonable levels of uncertainty about costs—vouchers perform better than price-linked subsidies. My results imply that, under the ACA, adopting a system of vouchers calibrated to the early years of the marketplaces would lead to sizable gains in terms of lower premiums and government spending.

5.2 More Subsidies for the Young Invincibles

The second counterfactual subsidy design amounts to providing additional enrollment incentives to the so-called “young invincibles”; in what follows this group consists of individuals aged between 26-35 (see e.g. [Levine and Mulligan, 2017](#)). Since these buyers are, at the same time, cheaper to cover and more price sensitive, lowering their (subsidized) premiums ignites a series of adjustments to a new equilibrium. Insurers lower base premiums, due to the average cost reduction and—under Nash pricing— increase in elasticity. Lower premiums lead to higher enrollment and higher consumer surplus. Importantly, since premiums across demographic groups are linked by rating regulations (which are hold fixed), the gains from higher subsidies to young individuals can be as large as to allow lowering subsidies for older individuals, while still keeping all buyers better off, increasing profits, and reducing per-buyer government spending.

There are many alternative ways to measure the benefit of higher subsidies to the young invincibles, and here I consider two. First, one can maintain a price-linked

Table 6: Counterfactual Subsidy Design: Shifting Generosity Toward “Young Invincibles”

Panel (a): Lowering MAA for under-35 by 30%

Note: Simulated market outcomes under alternative subsidy designs; for details on equilibrium computation, see note to Table 5. Panel (a) shows the effect of lowering the maximum affordable amount for individuals under-35 by 30%, holding fixed the other regulations as set under the ACA. Panel (b) compares the ACA-equivalent voucher to an alternative design in which vouchers for individuals under-35 are \$600 higher, while vouchers for individuals over-35 are \$100 lower. The Off-equilibrium columns show how outcomes vary when the subsidy design is changed, but base premiums are held fixed to the level of the ACA maximum affordable amount Equilibrium, and ACA-voucher Equilibrium, respectively. Total profits sum up profits across all insurers and year. Enrollment shares and annual per-person CS are computed as averages across region-years, weighted by number of eligible buyers. Other outcomes are enrollment-weighted averages.

design, and lower the maximum affordable amount (c.f. Section 2, Equation (1)) for young individuals. Second, using (equivalent) vouchers, one can increase vouchers for the “young”, while lowering vouchers for the “old”. For each alternative, the first-order, “off-equilibrium” effect of changing policy while holding base premiums fixed will be different than the equilibrium effect, which accounts for endogenous pricing behavior.

Panel (a) of Table 6 summarizes how marketplace outcomes respond to changing the ACA price-linked design by lowering the maximum affordable amount for young invincibles by 30%. In equilibrium, the effect is to increase enrollment in all demographic groups, as well as annual per-person consumer surplus, while average cost and average subsidies are lower. Despite slight differences in magnitude, the results are qualitatively similar under alternative models of insurer conduct.

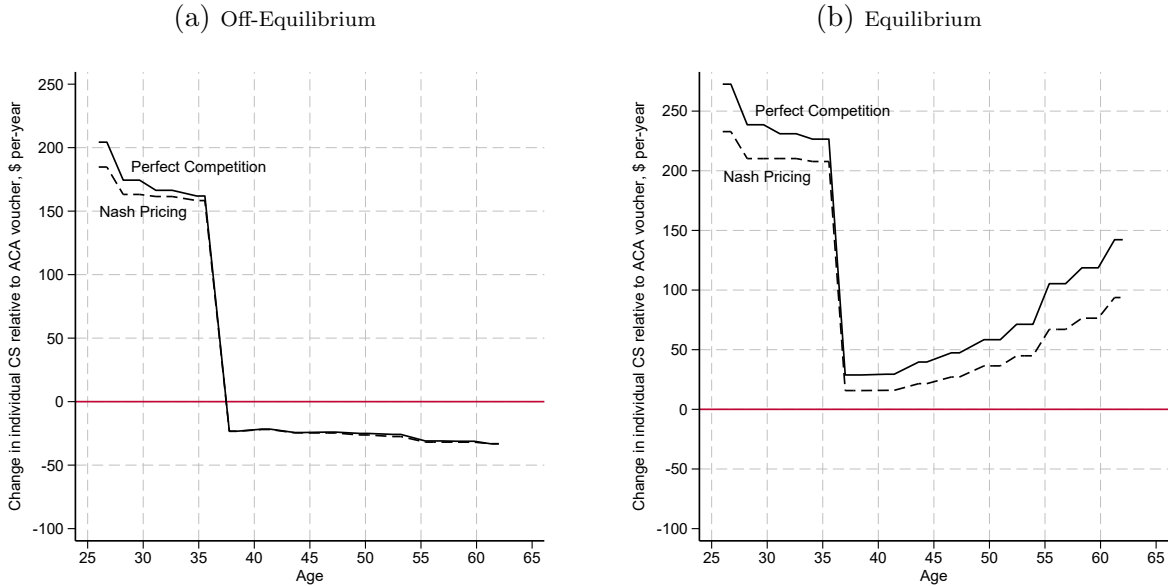

Using vouchers, the way in which alternative subsidy designs impact equilibrium outcomes is more intuitive. This is illustrated in panel (b) of Table 6, where ACA-equivalent vouchers are modified by raising annual under-35 vouchers by \$600, while lowering over-35 vouchers by \$100. Holding base premiums fixed, young invincibles would be better off, while older buyers worse off (the enrollment share for this group drops by 0.01 as they face higher premiums). In equilibrium, however, the reduction in base premiums following the larger enrollment share of under-35 individuals implies that all buyers are better off.

Considering Nash pricing, under-35 enrollment increases from 0.25 to 0.348, and over-35 enrollment from 0.304 to 0.312; despite receiving smaller vouchers, subsidized premiums of over-35 buyers are \$42 lower. The younger composition of enrollees translates in average costs that, in equilibrium, are 6% lower than under the ACA-equivalent voucher. Per-person consumer surplus increases by \$84 per-year, while average per-enrollee subsidies are \$53 lower. Profits are also higher since the increase in enrollment dominates the reduction in markups. The result by which the alternative vouchers represent an improvement for all buyers while not increasing average subsidies is robust to assuming perfect competition.

Figure 7 illustrates the relationship between age and changes in annual, per-person consumer surplus resulting from changing vouchers as in panel (b) of Table 6. The dash line corresponds to Nash pricing, while the solid line corresponds to the equilibrium simulations under perfect competition. In the left panel, base premiums are held fixed to the ACA-voucher equilibrium: under-35 experience a net gain, while over-35 are worse off. However, as shown in Figure 7b, at the new equilibrium the change in consumer surplus of over-35 switches sign: this group is now better relative to the ACA-voucher equilibrium, by an annual amount varying between \$10-100.²³

²³Due to the way in which rating adjustments amplify premium changes for older buyers, mid-aged individuals—while still better off—benefit the least from the alternative design. However, once established that everyone would gain, other alternatives in which vouchers are adjusted more granularly by age could smooth changes in consumer surplus across groups, while still ensuring lower premiums and lower average subsidies. Ultimately, design decisions depend on welfare weights, which here are not needed to argue that a design would improve upon the status-quo in terms of enrollment, profits, and consumer surplus.

Figure 7: Δ Consumer Surplus by Age: +\$600 Under-35 Voucher, -\$100 Over-35 Voucher

Note: Average annual change in per-person consumer surplus when replacing ACA-equivalent vouchers with vouchers that are \$600 higher for the under-35, and \$100 lower for the under-35. The left panel holds base premiums fixed to the equilibrium under ACA-equivalent vouchers, the right panel corresponds to the new equilibrium. The solid lines correspond to perfect competition à la [Azevedo and Gottlieb \(2017\)](#), the dashed lines correspond to Nash pricing.

6 Conclusion

Expanding coverage while limiting public costs is one of the main goals of government-sponsored health insurance. If individuals who value insurance less and are more responsive to premiums are also less risky, a subsidy design in which premiums are equal for all individuals can be worse than a design in which premiums vary across types. Adjusting subsidies to observables that predict preferences and cost can lead to equilibria in which all enrollees pay lower premiums, coverage and profits are higher, and average subsidies are lower.

After discussing this point, the article measured the potential gains from introducing age adjustments to ACA subsidies using data from the California marketplace regulated under the recent healthcare reform. The data supports oligopoly pricing over imperfect competition. Following the significant differences in preferences and cost across age groups, equilibrium simulations suggest that shifting subsidy generosity toward young uninsured would lower costs and premiums, increasing profits and consumer welfare. Whether this policy is desirable is a matter of political economy beyond the scope of my investigation.

To implement alternative subsidy schemes and to consider other market design and regulatory questions—e.g. the role of a public option, different risk adjustment

models, or quality regulations—future work could extend the model to account for dynamic or behavioral aspects, and for the key role played by healthcare providers. Access to richer data, including measures of health risk and healthcare utilization at the individual level, would facilitate the calculation of optimal policy parameters by researchers and policymakers.

Appendix

A Demand Model: Parametric Assumptions

The premium coefficient $\alpha_t(\mathbf{z})$ is allowed to vary across year, and across seven 6-years-wide age bins, and linearly with income. The coefficient on actuarial value $\beta_t(\mathbf{z}, \theta)$ is log-normally distributed with year-age-bin-specific parameters.

Letting $A^1 = \{26, \dots, 31\}$, $A^2 = \{32, \dots, 37\}$, ..., $A^6 = \{56, \dots, 61\}$, $A^7 = \{62, 63, 64\}$,

$$\alpha_t(\mathbf{z}) = \begin{cases} \alpha_t^{0,1} + \alpha_t^{1,1} z^{\text{Inc}} & \text{if } z^{\text{Age}} \in A^1 \\ \alpha_t^{0,2} + \alpha_t^{1,2} z^{\text{Inc}} & \text{if } z^{\text{Age}} \in A^2 \\ \dots & \\ \alpha_t^{0,7} + \alpha_t^{1,7} z^{\text{Inc}} & \text{if } z^{\text{Age}} \in A^7 \end{cases};$$

all parameters are year-specific.

The coefficient on actuarial value is log-normally distributed with year-age-bin-specific parameters:

$$\beta_t(\mathbf{z}, \theta) = \begin{cases} e^{\beta_t^1 + \sigma_t^1 \theta}, & \text{if } z^{\text{Age}} \in A^1 \\ \dots & \\ e^{\beta_t^7 + \sigma_t^7 \theta}, & \text{if } z^{\text{Age}} \in A^7 \end{cases}, \text{ where } \theta \sim G(\theta) = \mathcal{N}(0, 1);$$

\mathcal{N} indicates the standard normal distribution, θ and \mathbf{z} are independent:

$$G_{mt}(\mathbf{z}, \theta) = G_{mt}(\mathbf{z})G(\theta).$$

Figure 8: Estimated η^{WTP} varying assumptions on moral hazard

Note: The figure shows the estimated value of the adverse selection parameter η^{WTP} for different values of the moral hazard parameter ζ . The main results in the paper are obtained assuming $\zeta = 0$ (no moral hazard). The ACA risk adjustment model corresponds to $\zeta = 1$. $\zeta = 4$ (with results shown Table 7) corresponds to “400% ACA risk adjustment moral hazard”.

The term $\boldsymbol{\mu}_t(\mathbf{z})\mathbf{x}_{jmt}$ is equal to

$$\boldsymbol{\mu}_t(\mathbf{z})\mathbf{x}_{jmt} = \begin{cases} \mu_t^{0,1} + \mu_t^{1,1}z^{\text{Inc}} + \mu_t^{2,1}z^{\text{Age}} + \mu_t^{3,1}\text{HMO}_{jmt} + \boldsymbol{\mu}_t^{4,1}\text{Insurer}_{jmt} & \text{if } z^{\text{Age}} \in A^1 \\ \dots & \\ \mu_t^{0,7} + \mu_t^{1,7}z^{\text{Inc}} + \mu_t^{2,7}z^{\text{Age}} + \mu_t^{3,7}\text{HMO}_{jmt} + \boldsymbol{\mu}_t^{4,7}\text{Insurer}_{jmt} & \text{if } z^{\text{Age}} \in A^7 \end{cases};$$

this allows the value of marketplace coverage to vary piecewise linearly by year, age, and income, and the value of each product to vary—with year-age-bin parameters—with the type of provider network and insurer brand. Lastly, I let γ_t to be a cubic function of ξ_{jmt} , specific to every year and every age bin:

$$\gamma_t(\xi_{jmt}; \mathbf{z}) = \begin{cases} \gamma_t^{1,1}\xi_{jmt} + \gamma_t^{2,1}\xi_{jmt}^2 + \gamma_t^{3,1}\xi_{jmt}^3 & \text{if } z^{\text{Age}} \in A^1 \\ \dots & \\ \gamma_t^{1,7}\xi_{jmt} + \gamma_t^{2,7}\xi_{jmt}^2 + \gamma_t^{3,7}\xi_{jmt}^3 & \text{if } z^{\text{Age}} \in A^7 \end{cases}.$$

B Robustness to Moral Hazard

The cost estimates in Table 4 and the simulation results in Section 5 maintained the assumption of no moral hazard (see e.g. Einav and Finkelstein, 2018). This assumption is dictated by the lack of data to identify correlation between willingness-to-pay and

spending separately from the causal effect of coverage generosity on spending. In the model of Section 3, allowing spending to increase with actuarial value impacts the estimates of η^{WTP} and other cost parameters. Therefore, although the results above rely primarily on the fact that young uninsured individuals are generally healthy, the quantifications in Section 5 could be sensitive to different assumptions on moral hazard.

To address this, I re-estimate cost parameters and simulate policy counterfactuals under varying degrees of moral hazard. For reference, the ACA risk adjustment model (Pope et al., 2014) assumes that medical spending increases, on average, by 3% when the individual is covered under a Silver plan (without cost-sharing reductions) relative to the spending under a Bronze plan; by 8% when covered under a Gold plan, and by 15% when covered under a Platinum plan. These moral hazard parameters are consistent with the findings of Lavetti et al. (2019), who estimate that when cost-sharing reductions increase actuarial value from 70% to 87% (94%) total spending is 13% (19%) higher.

Formally, I let the expected claims associated with individual i enrolled in plan j , in region m , year t be equal to $\kappa_{jmt}^{\text{MH}}(\mathbf{z}_i, \theta_i) = AV_j^S L_{jmt}^{\text{MH}}(\mathbf{z}_i, \theta_i)$, with medical spending augmented for moral hazard defined as

$$L_{jmt}^{\text{MH}}(\mathbf{z}_i, \theta_i) = (1 + \zeta \times \chi_{ij}) L_{jmt}(\mathbf{z}_i, \theta_i), \quad (13)$$

where $\chi_{ij} = 0$ if $AV_{ij}^D < 70\%$, $\chi_{ij} = 0.03$ if $AV_{ij}^D \in [70\%, 75\%]$, $\chi_{ij} = 0.08$ if $AV_{ij}^D \in (75\%, 80\%]$, and $\chi_{ij} = 0.15$ if $AV_{ij}^D > 80\%$. $L_{jmt}(\mathbf{z}_i, \theta_i)$ is defined in Equation (5). If $\zeta = 0$, the model is identical to the one in Sections 3 and 5. Varying ζ , one can explore the sensitivity of my findings to the presence of moral hazard. When $\zeta = 1$, the model sets moral hazard to the level assumed by the ACA risk adjustment formula.

Figure 8 shows the estimates of η^{WTP} varying ζ . From the baseline level of $\eta^{\text{WTP}} = 0.07$ obtained when $\zeta = 0$, setting $\zeta = 1$ reduces this estimate by 3.7% ($\eta^{\text{WTP}} = 0.067$). The estimates of η^{WTP} remain above 0.06 as long as the level of moral hazard is lower than four times the level assumed by the ACA risk adjustment formula. To obtain $\eta^{\text{WTP}} = 0$, which would indicate the absence of adverse selection, one would need to set $\zeta = 13$, which seems quite unrealistic.

Table 7 explores the robustness of the results in Table 6 to alternative values of ζ . Considering the change in outcomes relative to the ACA-voucher equilibrium, the gains from increasing vouchers for young invincibles while lowering vouchers for older buyers remain present when assuming $\zeta = 1, 2$, or 4. Under perfect competition, the magnitude of the effects is almost invariant to ζ . Under Nash pricing, magnitudes are smaller when assuming larger degrees of moral hazard. However, even when setting

Table 7: Alternative Assumptions on Moral Hazard and Effect of Age Adjustments to Vouchers

Assumption on moral hazard:	Multi-product Nash						Perfect Competition					
	Change relative to ACA-voucher equilibrium +\$600 under-35 voucher, -\$100 over-35 voucher						Change relative to ACA-voucher equilibrium +\$600 under-35 voucher, -\$100 over-35 voucher					
	26-35 enrollment	36-64 enrollment	26-35 premium	36-64 premium	Average CS	Average subsidy	26-35 enrollment	36-64 enrollment	26-35 premium	36-64 premium	Average CS	Average subsidy
$\zeta = 0$	0.117	0.013	-552	-76	105	-68	0.133	0.022	-689	-175	129	0
$\zeta = 1$	0.114	0.011	-542	-50	98	-39	0.131	0.022	-684	-172	129	13
$\zeta = 2$	0.103	0.003	-477	18	78	-27	0.129	0.02	-675	-155	123	4
$\zeta = 4$	0.107	0.006	-495	-27	83	-48	0.128	0.02	-666	-149	121	-17

Note: The table shows how the results of panel (b) in Table 6 vary when allowing medical spending to respond to coverage generosity (moral hazard). For each value of ζ , cost parameters are estimated replacing L_{jmt} from Equation (5) with L_{jmt}^{MH} from Equation (13), and equilibrium simulations are obtained with the new cost parameters. For each outcome, the results in the table correspond to the difference between the ACA-voucher equilibrium column and the counterfactual voucher equilibrium column in Table 6.

$\zeta = 4$ the counterfactual vouchers make all buyers better off while reducing average subsidies.
